SUMMARY A patient with migraine who had a permanent visual field defect was studied by angiography and CT scan. He also had a tomographic study of cerebral blood flow (CBF) and oxygen extraction fraction (EO₂) using the non-invasive continuous oxygen-15 (¹⁵O) inhalation technique. Angiography was normal. CT scan revealed an area of decreased density with contrast enhancement suggestive of a recent infarct in the left occipital lobe. The ¹⁵O inhalation technique showed a decrease in CBF and EO₂, typical of recent infarcts, in the corresponding area, an increase in CBF with normal EO₂ in the left temporal lobe, and a decrease in CBF with increased EO₂ in the right occipital cortex. These findings illustrate the unusual nature and extent of the ischemic process underlying migrainous cerebral infarction.

LASTING NEUROLOGICAL DEFICITS, though infrequent, occur in migrainous subjects and are well documented by clinical, pathological, and, more recently, by computed cranial tomographic (CT) studies. We recently had the opportunity to study cerebral blood flow (CBF) and oxygen extraction fraction (EO₂) with the ¹⁵O inhalation technique coupled with positron emission tomography in a migrainous patient with a permanent visual field defect.

Clinical Summary

The patient is a 45-year-old right-handed man with a 25-year history of classical migraine. His attacks invariably began with blurring of vision, first intermittent for 2 or 3 min then stable for 10–15 min, followed by a left-sided or bi-temporal throbbing headache. The headache usually resolved in a few hours and was, on occasion, associated with photophobia and nausea. His attacks were infrequent (1 or 2 per year), generally mild, and no specific treatment was given.

One morning, without warning, he awoke with a complete loss of vision in the right visual field and a moderate left-sided headache. He had no dysphasia, paresthesia or weakness. The headache gradually worsened becoming generalized and excruciatingly painful and was accompanied by vomiting. His headache resolved over the succeeding 4 days, after which visual loss decreased.

Examination of his visual fields by confrontation 12 days later, revealed a right homonymous hemianopsia to finger movement, more dense in the upper quadrant. The left visual field was entirely normal. Blood pressure was 130/80 mm Hg. There was neither cervical nor cranial bruit.

Investigations

Normal laboratory studies included complete blood count, platelet count, serum electrolytes, sedimentation rate, blood urea nitrogen, glucose, creatinine, total protein, albumin, serum cholesterol, and triglycerides, serum glutamic oxaloacetic transaminases, alkaline phosphatases, urinalysis, and serologic tests for syphilis. His electrocardiogram, echocardiogram, chest and skull roentgenograms were also normal. His electroencephalogram showed abnormally slow activity over the posterior region of the left hemisphere.

CT scan, performed 18 days after onset, showed in the left occipital region an area of decreased density — approximately 30 mm × 60 mm in size — (fig. 2A) which markedly enhanced following the infusion of contrast material (fig. 2B). In the left temporal region, there was a large, ill-defined but definite area of decreased density (fig. 2C) with neither contrast enhancement nor mass effect.

Four vessel-angiography, 21 days after onset, was normal.

CBF and EO₂ (EO₂ is the oxygen arterio-venous difference divided by the arterial oxygen content) were measured 14 days after the onset of symptoms, with ¹⁵O₂ and C¹⁵O₂ continuous inhalation associated with
positron emission tomography, using the model proposed by Jones and the technique described by Baron. This method, already applied to normals and to patients with ischemic brain disorders, will therefore not be described in detail here. For each transaxial brain level (studied at an angle of + 5° from the orbito-meatal (OM) line), a set of 3 different images is obtained: 1) a $C^{16}O_2$ image which represents CBF, 2) a $O_2$ image which represents both oxygen metabolism and CBF, and 3) a $C^{15}O_2/^{16}O_2$ ratio image which is linearly proportional to $E_2$. In the $C^{16}O_2$ and $O_2$ images obtained in this patient, count rates per unit volume were calculated for various identical regions of interest. Each value was compared to that of the homologous contralateral area or to that of the ipsilateral hemisphere and was considered abnormal if the difference was outside the confidence limits defined by 6 normal patients. The same procedure was applied to the value obtained by dividing the $O_2$ count rate by the $C^{16}O_2$ count rate, i.e. a value linearly proportional to $E_2$.

On slices obtained 5.5 cm above the OM plane,
striking abnormalities were observed (fig. 3):

1) an increase in activity of similar magnitude (p < 0.01) on both the C15O2 (+ 15.5%) and 15O2 images (17.2%) without significant change in the 15O2/C15O2 ratio value in the left temporo-Sylvian area.

2) a decrease in C15O2 activity of similar magnitude (p < 0.01) in the left (-15.3%) and right (-14.6%) occipital regions associated with a) on the left side, a significant (p < 0.01) decrease in 15O2 activity (-33.5%) and in 15O2/C15O2 ratio value (-17.5%); b) on the right side, an unchanged 15O2 activity (+3.4%, p > 0.05) but an increased 15O2/C15O2 ratio value (+11.2% p < 0.01). On the slice OM + 7.5 cm, all images were normal. (fig. 3)

Discussion

This patient had typical migraine with a long past history, an acute onset of a neurological deficit during a severe attack of migraine, and the partial resolution of symptoms leaving a permanent neurological deficit. The visual field defect in our patient is similar to that reported by Mallory and shown by Polyak to be due to a small infarct in the lower margin of the calcarine fissure.

Angiography performed 21 days after the onset of symptoms was normal, as is often the case in migraine, although in rare instances occlusion of the posterior cerebral artery or its branches has been observed.

The diagnosis of cerebral infarction in our patient was made on the basis of the CT scan. Performed 18 days after the onset of symptoms, it showed an area of decreased density with contrast enhancement in the left occipital lobe (fig. 2 A-B). This pattern of anomaly, without mass effect, is typical of recent infarcts and has already been described in complicated migraine. A more common finding in this condition is, however, a region of low density without contrast enhancement, even observed occasionally in patients studied less than 10 days after onset.

The other interesting finding on the CT scan was a definite decrease in density without contrast enhancement in the temporal lobe (fig. 2C) suggesting a disturbance in the territory of the middle cerebral artery with no clinical counterpart.

The main findings of interest are the tomographic studies of CBF and EO2 with the 15O continuous inhalation. Although indisputable experimental verification of the validity of the CBF and EO2 measurements obtained with this technique has not yet been reported, there is, however, ample indirect evidence in humans that the tracer distribution in the C15O2 image is a reflection of CBF and that the 15O2/C15O2 ratio image is a representation of the EO2.

Results obtained from normal subjects and in patients with different pathological conditions suggest that the EO2, which is normally uniformly distributed, could be an important pathophysiologic parameter and even have a prognostic significance when studied concomitantly with CBF.

The 15O inhalation study performed 14 days after the onset of symptoms, showed 3 disturbance patterns:

1) EO2 was decreased in the left occipital cortex strongly suggesting a focally decreased oxygen arteriovenous difference: this situation has been called "luxury perfusion" by Lassen. CBF, though decreased, was still over-abundant compared to the local metabolic demand since EO2 was decreased, thus indicating a relative luxury perfusion. Such a focally decreased EO2 has been observed in 82% of recent (less than 31 days) infarcts. This possible uncoupling of CBF and metabolism has never been reported in complicated migraine. It differs strikingly from the areas of reduced CBF usually observed during the prodromal phase of classical attacks. It may, however, be related to the focal areas of high flow described by Marshall in cases of migraine without headache but none of his patients had their cerebral metabolism studied. It is possible that patient 2 reported by Dorfman also had a luxury perfusion since angiography showed arterio-venous shunting 4 days after the attack. Such an alteration was not seen in our patient, possibly because angiography was performed too late (3 weeks after the attack and a week after the CBF study). It should be noted that the decrease in CBF observed here was associated with CT contrast enhancement, thus illustrating that contrast enhancement does not necessarily imply increased perfusion. Other mechanisms must be involved, among them the breakdown of blood-brain barrier.

2) CBF was increased in the left temporal lobe contrasting with a normal EO2. This increase in CBF...
reflects an actual change of higher magnitude because of the underestimation of high values due to the non-linear relationship which exists between the count rate and CBF. However, such a focal hyperemia has been detected in a number of clinical situations by this technique. It probably corresponds to the situation described experimentally as "reactive hyperemia" or "supernormal blood flow," which is observed after acute ischemia when flow is restored. Thus, there may have been in our patient a transient ischemia in the left middle cerebral artery territory. It is interesting to note that this hyperemic region appears hypodense on CT scan, but appears without contrast enhancement.

3) CBF was decreased but EO₂ increased in the posterior part of the right occipital cortex, indicating a situation of "supernormal oxygen extraction" for which we presently have no satisfactory explanation. Although all his previous attacks were characterized by blurring of vision in both visual fields, the patient denied any disturbance in the left visual field during the present attack of complicated migraine.

These observations show that the cerebral lesion responsible for the permanent visual loss has not only the same CT scan characteristics as an infarct, but also the same pattern of hemodynamic and metabolic disturbances, i.e., a luxury perfusion. They also show an increase in CBF and an increase in EO₂ respectively in the left temporal lobe and in the right occipital cortex suggesting an involvement, latent clinically, of the corresponding arterial territories and thus stressing the unusual nature and extent of the underlying process.

Acknowledgment

We thank most warmly for helpful advice and criticism Dr. R. W. Ross Russell (Institute of Neurology, London) who kindly revised the manuscript. The skilled technical assistance of N. Duquesnoy, J. Sastre, C. Loc’h is also gratefully acknowledged.
