SUMMARY Regional brain tissue prostaglandin (PG) levels have been measured during ischaemia produced by bilateral carotid occlusion for 1 hour and following restoration of flow. In the normal gerbil, the frontal cortical levels of PGE$_2$, were: 6.7 ± 1.3 pg/mg and for PGE$_2$: 6.4 ± 1.1 pg/mg of brain tissue protein. Following 1 hour of ischaemia PGE$_2$, rose to 50.4 ± 8.3 pg/mg whilst there was only a slight rise in PGE$_2$ (10.7 ± 1.6 pg/mg). Post ischaemic values for parietal and occipital areas were somewhat higher, but showed the same trend. Within 15 minutes of the restoration of flow there was a massive increase in PGE$_2$, levels which reached a peak at 2 hours (300 pg/mg) and then subsided to control values. PGE$_2$, levels did not change for the first 30 minutes of recirculation, but then rose for the rest of the period of observation. The pattern of cytotoxic oedema resembled PGE$_2$, closely while the Evans blue staining (vasogenic oedema) was similar in time to the PGE$_2$, pattern.

THE DISRUPTION OF CELLS due to trauma or ischaemia may release a wide variety of compounds causing profound vascular effects. The breakdown of the membrane also produces vasoactive compounds and it has been suggested that the release of polysaturated fatty acids (PUFAs) or their metabolites may be implicated in the development of oedema. In previous work we have shown that pretreatment of our gerbil model with a cyclooxygenase inhibitor, indomethacin, which inhibits arachidonic acid metabolism, significantly reduced the amount of oedema accumulating in severely ischaemic brain tissue. This only occurred at cerebral blood flows below which a massive efflux of potassium has been demonstrated and has been taken as evidence of cell membrane disruption.

The effect of restoration of flow has also been studied, and we have shown that there is an acceleration of water accumulation in severely ischaemic brain following recirculation. This precedes the leakage of protein linked markers such as Evans blue. The source of the water is the vascular system but the initiating mechanisms for the water accumulation or leakage of Evans blue are far from clear. If the products of cell disruption are implicated in ischaemic oedema, may they also be involved during reperfusion? Might these compounds produced by ischaemia interact with the recirculating blood and further aggravate the situation?

The purpose of this study has been to measure the production of prostaglandins (PG) during ischaemia and recirculation to determine if there is a time relationship with oedema formation during reperfusion.

Methods and Materials

A) Surgical Preparation

Adult male gerbils (Meriones unguiculatus, 50–60g) were used in all experiments. Surgical preparations, carotid ligation, thoracotomy, "kill" perfusion and dissection of brain were performed in an identical fashion in all animals, as previously described. Animals were anaesthetised with pentobarbital (60 mg/kg) intraperitoneally and a microscopic dissection of the neck performed to allow simultaneous occlusion of both carotid arteries with Scoville aneurysm clips. Exactly 1 hour after bilateral carotid occlusion, aneurysm clips were removed and the cerebral circulation restored for varying periods of time for up to 3 hours. A thoracotomy involving removal of the sternum allowed access to the heart. This enabled the "kill" perfused technique to be effected; the right atrium was opened, the descending aorta occluded and a cannula inserted into the left ventricle. A combination of heart beat and hydrostatic pressure allowed perfusion of the upper half of the gerbil body using a cold solution of indomethacin/saline (10 µg/ml) for a period of 2 minutes. The brain was then rapidly removed and dissected in a Petri dish containing the same solution, the whole procedure taking less than 1 minute. The frontal lobes were dissected anterior to the optic chiasm with removal of the olfactory bulbs. Parietal cortex was dissected external to the lateral ventricles in order to exclude any deep grey matter. The portion of the occipital lobe chosen was the posterior-inferior part of the cerebral hemisphere. Samples from all areas were cut cleanly with a sharp scalpel and then rapidly frozen in liquid nitrogen. Similar sample sizes were obtained from each area, approximately 70 mg in weight, variation being avoided as far as possible in order to allow similar dilutions for radioimmunoassay and protein estimations.

The technique of "kill" perfusion was considered to be important in order to biochemically "freeze" (vida infra) the synthesis of PGs by the tissue during sampling. For the ischaemia model, the clips were not removed from the carotid arteries, unlike the reperfusion model.
B) Prostaglandin Extraction and Assay

Samples were sonicated using an M.S.E. ultrasonicicator at maximum amplitude for 10 seconds in an ice-cold solution of citric acid (pH 3.5), and indomethacin (10 μg/ml). Addition of 1000 dpm of (H) PGF$_{2\alpha}$ (180Ci/mmol) and (H) PGE$_2$ (120Ci/mmol) (Amersham International U.K.) were employed as internal standards. The samples were extracted twice in 8 volumes of cyclohexane:ethylacetate (1:1 v/v) and after centrifugation at 2000 g, the solvent layers were pooled and stored at −20°C under nitrogen for up to 24 hours. The solvents were evaporated to dryness under reduced pressure and the residue taken up in 1 ml cyclohexane:ethylacetate:methanol (60:40:0.2).

Due to the known interference of nonesterified fatty acids in radioimmunooassays, it was necessary to separate the PGs by column chromatography on activated silicic acid (0.5g, 100 mesh Mallinkrodt) using the following solvents:

1. (1) 5 ml cyclohexane:ethylacetate (60:40), to remove nonpolar lipids;
2. (2) 10 ml cyclohexane:ethylacetate:methanol (60:40:2), to elute PGE$_2$;
3. (3) 5 ml (60:40:20), to elute PGF$_{2\alpha}$.

The various fractions were again evaporated under vacuum, taken up in 1 ml 0.1M phosphate buffer at pH 7.4 (0.9% NaCl), 1% gelatin and 1% Sodium azide w/v and kept at 4°C for 2 hours. Recovery estimated by internal standards was 63 ± 10 (mean ± S.D.) for both PGF$_{2\alpha}$ and PGE$_2$, through the whole extraction and separation procedure. Both were measured by radioimmunoassay at three different dilutions (1:10, 1:150, 1:100) in order to utilise the linear portion of the standard calibration curves. Anti PGE$_2$ and PGF$_{2\alpha}$ antisera were purchased from Sigma (London) and found to be of high specificity and low cross-reactivity, which was further enhanced by the separation procedure. The specificity of the determination with respect to cross-reactivity between the PGF$_{2\alpha}$ and PGE$_2$ was as follows. Recovery for PGE$_2$ in the 60:40:2 fraction by radioimmunooassay was 95%, and 2% for PGF$_{2\alpha}$ whereas 90% recovery was obtained for PGF$_{2\alpha}$ with the 60:40:20 fraction, with no binding for PGE$_2$. After incubation and charcoal separation, the unbound radioactive ligands were counted by liquid scintillation on a Beckman LT 3150, with a counting efficiency of 90% recovery was obtained for PGF$_{2\alpha}$ with 100%.

Table 1 summarizes the effect of bilateral carotid ligation on PG levels as compared to control animals. Saline perfusion alone reduces the PG levels in the gerbil brain but not to the same extent as that seen with indomethacin/saline perfusion. The control results were lower than those reported by others and indicates the importance of the vascular compartment as a source of PGs.

Brain cortical PG levels in control animals and those perfused with either saline alone or indomethacin/saline (10 μg/ml). The perfusion solution was maintained at 4°C. There was a significant decrease in both classes of PGs following perfusion especially with indomethacin/saline.

Absolute results expressed in pg/mg tissue protein.

Relative results expressed as percentage with control assumed at 100%.

n = 3 for each group.
rCBF was estimated by the hydrogen clearance technique, showed a marked reduction following bilateral carotid occlusion for 1 hour. There was a gradation in ischaemic flow from frontal to the occipital regions.

Time Course of PG Synthesis During Reperfusion

The effect of bilateral carotid occlusion in the gerbil, for 1 hour following by reperfusion for periods of up to 3 hours on PGF2α and PGE2 content is shown in figure 1. There was a gradation in permeability and transport capabilities.

Changes in Specific Gravity Measurements During Reperfusion

Figure 2 depicts the changes in specific gravity (SG) measurements during reperfusion following 1 hour of ischaemia represented by the parietal region. The profiles were similar in the other areas; frontal and occipital regions.

During 1 hour of ischaemia, all areas showed a significant fall in SG (increase in oedema). There was, further, a more rapid accumulation of oedema within 5 minutes of clip removal. The fall in SG was most frequently bilateral and symmetrical, staining the deep grey structures.

Discussion

During the process of phospholipid deacylation in ischaemia, the release of arachidonic acid AA may be monitored by measuring the metabolites, namely the PGs. Hence changes in PG levels are possible indications of membrane degradation and therefore reflect changes in permeability and transport capabilities.

Measurement of tissue PG levels may be complicated by the rapid synthesis of PGs during the process of sampling, and special precautions are required to prevent this artefact. In this study we describe a method of "biochemically freezing" the PG levels in situ during sampling, and the "kill" perfusion technique which we have also described has provided reliable and reproducible results showing significant differences in relatively small changes in PG levels with minimal error arising from tissue handling during the sampling procedure (see table 1). The technique "washes out" the vascular compartment and we consider that most of the PGs measured are derived from brain tissue during the ischaemic insult.

During periods of ischaemia the increased synthesis, as evidenced by high tissue levels of PGs, probably indicates an increased availability of substrate, (AA), derived from the breakdown of membranes. Metabolism of AA to PGs via cyclic endoperoxides is dependent upon a number of factors. These include oxygen availability and hence blood flow. The differential and much smaller rise in PGE2, as compared to the six-fold increase in PGF2α may itself be due to...
several factors, one of which may be differences in the normal Michaelis-Menten kinetics of the PG isomerases involved (vida infra). Another possibility may be the distribution of these enzymes within the brain tissues. Wolfe\textsuperscript{13} reported a similar differential synthesis of PGE\textsubscript{2} and PGF\textsubscript{2}\alpha in brain homogenates and tissue slices. PGE\textsubscript{2} synthesis reached completion within 15 minutes of incubation whereas PGF\textsubscript{2}\alpha synthesis continued for up to 1 hour. Our data during ischaemia are similar but the results following reperfusion could not be explained in this fashion. With the restoration of cerebral flow there is a 40-fold increase in PGF\textsubscript{2}\alpha which reaches peak values within 1 hour, thereafter declining to levels found with ischaemia alone (Figure 1). With reperfusion PGE\textsubscript{2} levels do rise by tenfold but only after a delay of 2 hours. It might be postulated that the relatively larger response of PGF\textsubscript{2}\alpha is due to the sensitivity of PGE-isomerase to high substrate concentrations,\textsuperscript{14} and it might also be argued that if our observations during ischaemia alone had extended over the same time as the recirculation experiments then a similar pattern would have emerged. As the amount of AA was depleted, so the inhibition of the enzyme would have been reduced, thus allowing greater production of PGE\textsubscript{2}. At the same time PGF\textsubscript{2}\alpha synthesis would continue to fall due to a decrease in substrate concentration, following a normal Michaelis-Menten pattern of enzyme kinetics. An argument against this explanation is found in Gaudet and Levine's\textsuperscript{15} work with 1 to 30 minutes occlusion in gerbils, in which they found only a transient increase in PGE\textsubscript{2}, but this, too, is unlikely due to the low PG-dehydrogenase activity in brain compared with other tissues.\textsuperscript{16} A third explanation could be that of the "washout" of PGs into the vascular compartment either by simple diffusion or by a saturable facilitated transport mechanism.\textsuperscript{17} This, however, could not account for the results obtained during ischaemia alone, due to reduced blood flows.

What is increasingly emphasised in ischaemic damage to the nervous system is that the depth of ischaemia and the duration of the insult are important.\textsuperscript{18} It appears that a 5 or 15 minute interruption of carotid flow can be well tolerated with practically no mortality or morbidity. A 30 minute occlusion followed by reperfusion has a mortality of 40% at 24 hours,\textsuperscript{18} whereas occlusion for

Evolution of EB leakage following 60 minutes of bilateral cerebral ischaemia and reperfusion. Results expressed as ratio of animals with EB extravasation over the total gerbils per group. There is no sign of EB until the first hour but increases rapidly to 50% by the second hour. The EB seen in animals at the third hour is greater in degree as compared to those at two hours of reperfusion.
1 hour produces a 93% mortality over the same period. In the model we have chosen, there is extensive infarction in the few survivors while in the 1 to 30 minute model used by Gaudet and Levine there may be minimal disruption of cerebral architecture. Our results therefore are not at variance with theirs but represent the other end of an ischaemic spectrum. Nevertheless, there are significant differences in the results of our two groups, and other explanations need to be sought.

With respect to Evans blue studies, as shown by others and ourselves, there is no leakage of dye from the vascular compartment following a 5 minute occlusion and only an occasional example with 15 minute carotid interruption at 24 hours of reperfusion; but following 60 minutes of ischaemia 50% show EB staining of tissues within 120 minutes of reperfusion (see table 3). This would suggest a profound alteration in the blood brain barrier (BBB) following ischaemia of this length and depth during which intravascular substances will leak out into the damaged tissue, leading to situations different from those obtained in the shorter occlusion times. It must be borne in mind that EB staining provides a gross marker rather than a sensitive one, therefore, its incidence would only be expected in extensive BBB damage, although disruption to the vasculature has been shown to occur to a lesser degree much earlier over a larger area using a sensitive marker such as sucrose extravasation.

We were impressed by the similar time scales for the elevation of PGE$_2$ and the appearance of EB staining, and we postulate that the phenomena may be causally related. PGE$_2$ is a major product of the microcirculation in bovine brain, and Pickard has shown that PGE$_2$ represents up to 50% of AA metabolism in canine cerebral arteries. It may be that in our model of prolonged and profound ischaemia there is vascular endothelial damage which gives rise to PGs when reperfusion occurs. The vascular damage will then result in breakdown of the BBB and intravascularly generated PGs will "leak" into brain tissue and be measured by our technique. The question then arises as to whether the breakdown of the BBB and endothelial PG generation are two separate effects of the ischaemic insult, or whether they are related. Clearly, more work will be required to substantiate this relationship.

Our main conclusion so far, is that following the restoration of flow in severely ischaemic brain there is a rapid production of PGE$_2$, the profile of which resembles that of brain water content over the same period in the same model. By contrast, the increase in PGE$_2$ is delayed but progressive, and is not found in shorter periods of ischaemia which in turn are not mortal in the gerbil and not associated with Evans blue extravasation.
