Actinomycin D Suppresses The Protective Effect Of Dexamethasone In Rats Affected By Global Cerebral Ischemia

ÁRPÁD TÓSAKI, PH.D., MÁTYÁS KOLTAI, M.D., FERENC JOÓ, M.D.,† GÉZA ÁDÁM, B.Sc.,† PÉTER SZERDAHELYI, PH.D., István LEPRÁN, PH.D., ISTVÁN TAKÁTS, PH.D., and LÁSZLÓ SZEKERES, M.D., D.Sc.

SUMMARY Simultaneous occlusion of both common carotid arteries in female Sprague-Dawley CFY rats produced characteristic symptoms of global cerebral ischemia, such as staggering, circling, convulsions, followed by coma and death. A close correlation existed among these symptoms and the elevation of water and Na⁺ content, appearing at the stage of staggering; Evans blue extravasation and diminution of K⁺ content in the total brain tissue, manifesting itself at the phase of convulsions, indicating the development of cerebral edema due to ischemia. Dexamethasone given subcutaneously in a single 2.0 mg kg⁻¹ dose 5 hours prior to the induction of global cerebral ischemia reduced considerably the morbidity and mortality, the alterations in water and electrolyte content, and albumin leakage in the brain tissue. Actinomycin D, in a dose of 0.5 mg kg⁻¹ injected intravenously 1 hour before steroid treatment, abolished the beneficial effect. This finding suggests that de novo protein synthesis is involved in the cerebroprotective effect of dexamethasone.

SEVERAL CLINICAL TRIALS HAVE shown that glucocorticoids exert a beneficial effect in patients with cerebral ischemia and brain injuries. 1,3–5 On the other hand, Bauer and Tellez 4 have described opposite results. Brain disorders of other types than trauma, (e.g. cerebral malaria) do not provide any evidence for the benefit of steroid treatment. 5 Experimental results obtained in different animals with various types of brain injuries have supported the assumption that ste-
blood brain barrier resulting in brain edemas of cytotoxic, and vasogenic types. In the light of experiences with steroid therapy, the conclusion may be drawn that the functional disturbances associated with injury to the brain do not necessarily develop as a consequence of edematous processes. The controversial data concerning cerebral ischemia may lead us to a similar conclusion.

For a more effective therapeutic intervention in the ischemic disorders of the brain, the animal model used and the principles of causal therapy should be better outlined. This requires a more exact knowledge of their pathogenesis and a deeper insight into the mechanism of drug action.

Although bilateral common carotid artery occlusion is known to be insufficient to induce progressive global cerebral ischemia in the great majority of rat strains, in a preliminary study we have found, surprisingly, that this intervention could lead to fatal brain damage provided that the surgery was performed on Sprague-Dawley rats of CFY strain. Detailed pathophysiologic and neuropathologic characterization of the model is in progress in our laboratory.

We report here that the simultaneous occlusion of both common carotid arteries in female Sprague-Dawley rats of CFY strain produces characteristic symptoms of global cerebral ischemia which correlate well with changes in water, electrolyte, and albumin content of brain tissue. Dexamethasone provides marked protection against these alterations, and its effect may be related to de novo synthesis of some cerebroprotective protein factors.

Methods

A close colony of randomly-bred female Sprague-Dawley CFY rats weighing 200–220 g, fed commercial food pellets and tap water ad libitum, was used. The rats proved to be normotensive on the basis of blood pressure measurement from the cannulated left common carotid artery under pentobarbitone anesthesia (30 mg kg⁻¹ intraperitoneally, Mebubarbital sodique, Rhône-Poulenc) and on the cuffed tail artery test in an awake condition.

In the first experiment, the mortality rate and the appearance of the symptoms, being characteristic of global cerebral ischemia, were determined. The rats were divided into 4 groups: (i) carotid artery ligated animals given a subcutaneous bolus of 1.0 ml kg⁻¹ isotonic saline served as controls; (ii) one group was treated with 1.0 or 2.0 mg kg⁻¹ dexamethasone di-phosphate (Oradexon, Organon) at various time intervals prior to the induction of cerebral ischemia; (iii) actinomycin D (Merck, Sharpe, and Dohme) in a dose of 0.5 mg kg⁻¹ was administered into the tail vein 6 hours before carotid artery occlusion to another group; (iv) finally, dexamethasone treatment was combined with actinomycin D given 1 hour prior to the steroid. In some cases, the behavior of sham-operated animals without bilateral common carotid artery ligation was also studied.

In the second experiment, 4 groups of 6 rats with bilateral carotid artery ligation were used for the determination of water, Na⁺, K⁺, Ca²⁺ and albumin content of the brain tissue. Sham operated rats without carotid artery occlusion served as controls in this study. The rats were killed by decapitation at the time when the different symptoms developed. The whole brain was removed and its wet weight was immediately measured. The tissue was then dried at 110°C for 40 hours to obtain its dry weight. Water content was expressed as a percent of the total dry tissue weight. To determine electrolyte contents, the dry tissue was ashed at 550°C for 20 hours. The ash was dissolved in 5 ml 3 M nitric acid (Merck, Suprapur®), and diluted 10-fold with deionized water. Na⁺ was measured at the wavelength of 330.3 nm K⁺ at 404.4 nm, and Ca²⁺ at 422.7 nm in an air-acetylene flame by a Perkins-Elmer 306 atomic absorption spectrophotometer. The slit width was 0.7 mm in all measurements. The value determined at the time of the appearance of the symptoms of cerebral ischemia after various pretreatments of the rats were expressed mmol kg⁻¹ dry weight.

The determination of Evans blue dye was performed according to Rossner and Tempel. In brief, the rats were injected intravenously with Evans blue (Sigma, 2.0% w/v) in a dose of 20 mg kg⁻¹ body weight 2 hours before the appearance of characteristic symptoms. They were then sacrificed by opening the chest wall under ether anesthesia. In order to remove the intravascularly localized dye, a polyethylene tube was inserted into the aorta through the left ventricle, and a perfusion with isotonic saline until colorless perfusion fluid was obtained from the right atrium was made. The whole brain was removed and weighed, then homogenized in 1 ml 50% trichloroacetic acid (w/v), and centrifuged with 10,000 g for 30 min. The absorbance of the supernatant was determined at 615 nm by a Unicam SP 1800 ultraviolet spectrophotometer. The results were expressed as µg g⁻¹ wet weight.

Statistical analysis of the mortality rate was made by the Chi-square method. The appearance of staggering and the alterations in water, electrolyte, and Evans blue content in the brain tissue were statistically evaluated by the unpaired Student’s t-test.

Results

Preliminary observations in our laboratory have indicated that simultaneous ligation of both common carotid arteries in female Sprague-Dawley CFY rats (n = 325) produces death within 12 hours in two-thirds of the animals. This period was long enough to detect behavioral changes and clearly distinguishable symptoms developing as a result of global cerebral ischemia. The first characteristic symptom was staggering that appeared at 146 ± 4.7 min (table 1) circling ensued at 268 ± 5.6 min, followed by convulsions at 361 ± 16.6 min, then deep coma developed. As the first symptom occurred, the process was irreversible, and the rats died. Male rats were less sensitive to carotid artery clamping than females. Sham-operated animals without bilateral common carotid artery ligation did not develop any symptoms. Under pentobarbi-
In the saline-treated group, carotid artery ligation significantly elevated the water, Na⁺ and Evans blue content of total brain tissue as compared to sham-operated animals, and these changes showed a close correlation with the symptoms which appeared at different stages of global cerebral ischemia (tables 1 and 2). Water and Na⁺ content was already increased in the rats affected by staggering, while extravasation of Evans blue dye was detected only at the second stage of ischemia. K⁺ changed in the opposite direction, and its decrease was less obvious at the beginning of ischemia, while in later stages it became excessive (table 3). Ca²⁺ concentration was only slightly decreased during the appearance of the first two symptoms, when convulsions appeared however there was a sharp elevation in its level (table 3). The alterations in water, electrolyte and Evans blue content of brain tissue provided evidence for a gradually and continually developing severe cerebral edema. In the dexamethasone treated group in which the samples were taken at the time when the symptoms appeared in the controls, all metabolic and blood brain barrier alterations were markedly suppressed (tables 1 and 2). In the rats treated with actinomycin D alone, the water, electrolyte, and Evans blue contents exhibited alterations of the same direction and almost of the same extent as measured in controls (tables 1 and 2). Actinomycin D treatment prevented the dexamethasone-induced protective effect on these parameters.

**Discussion**

The results reported here indicate that bilateral carotid artery occlusion in female rats, originated from a closed colony of Sprague-Dawley CFY strain, pro- duces characteristic symptoms of global cerebral ischemia that correlate well with the development of brain edema. These findings are in accordance with that found by Lespinase et al. with bilateral internal carotid artery clamping in Long Evans rats. Nakatomi et al. have shown that spontaneous hypertensive male

rats are more sensitive than females to metabolic changes evoked by bilateral carotid artery occlusion. The sex difference between their hypertensive and our normotensive rats in response to cerebral ischemia has not been clarified yet.

Our study clearly shows that a single dose of dexamethasone protects the rats against the development of symptoms and the lethal complications of bilateral carotid artery occlusion. The synthetic glucocorticoid appears to protect the rats against cerebral edema as well. These findings confirm findings shown by Bartko et al19 and Okamatsu et al20 in response to the occlusion of middle cerebral artery in cats. The time course of the protective effect observed in our experiments resembles that found by Church and Miller,20 who studied various inflammatory responses, since the cerebroprotective effect of dexamethasone develops after 5 hour-lag phase.

We also found that actinomycin D, an inhibitor of messenger RNA synthesis,21 completely abolished the protection provided by the synthetic glucocorticoid. This finding strongly suggests that de novo protein synthesis is involved in the cerebro-protective effect of dexamethasone.

Anti-inflammatory glucocorticoids have been shown to induce the synthesis of an antiphospholipase A2 polypeptide named macrocortin22-25 or lipomodulin26,27 in non-neuronal tissues. In this context, actinomycin D has recently been found to prevent the cardioprotective effect of dexamethasone28 and parenteral administration of macrocortin has been described to provide marked protection against sudden cardiac death in coronary ligated conscious rats.29 It appears, therefore, likely that macrocortin induces cardioprotection by preventing the formation of arachidonate metabolites. These metabolites were found to be produced in isolated brain microvessels as well.30 It has also been demonstrated that platelet hyperaggregability contributes to the development of ischemic cerebrovascular diseases.31 Although direct evidence for the role of glucocorticoid-induced mediators in the control of stroke has not been available, the present study suggests that second messengers of steroid action might provide protection also against fatal cerebral ischemia.

Effect of Common Carotid Occlusion on β-Adrenergic Receptor Function in Cerebral Microvessels

Maria Sandra Magnoni, Ph.D., Hideyuki Kobayashi, Ph.D.,* Ludovico Frattola, M.D., Pier Franco Spano, Ph.D., and Marco Trabucchi, M.D.

SUMMARY β-adrenergic receptors were measured in cerebral microvessels of gerbils and rats after ligation of the right or left common carotid artery. The results indicate a decrease in the number of β-adrenergic receptors in brain microvessels of both ipsilateral and contralateral hemispheres. This event may reflect altered patterns of the neuronal regulation of brain microvasculature and may be related to cerebrovascular alterations which are concomitant with ischemia. Furthermore, the results show that the decrease in β-receptor density is more pronounced in the left hemisphere, independently on the side of carotid occlusion. This finding suggests that microvessel function in the left side of the brain is more vulnerable to hypoxia effects.

Actinomycin D suppresses the protective effect of dexamethasone in rats affected by global cerebral ischemia.
