Regional Cerebral Blood Flow, Glucose Metabolism, Protein Synthesis, Serum Protein Extravasation, and Content of Biochemical Substrates in Stroke-Prone Spontaneously Hypertensive Rats

W. Paschen, G. Mies, W. Bodsch, Y. Yamori,* and K.-A. Hossmann

SUMMARY Stroke-prone spontaneously hypertensive rats with arterial blood pressure above 210 mmHg were taken for the present study after appearance of neurological symptoms. Regional cerebral blood flow, glucose metabolism, and protein synthesis rate were evaluated on the same brain section by means of triple-labelled autoradiographic techniques. Consecutive sections were used in the pictorial presentation of glucose, ATP, and serum protein extravasation. In addition, NADH-fluorescence was recorded.

Two different patterns of hypertension-induced brain lesions could be distinguished: In two animals sharply demarcated cysts were visible in the cortical grey matter. In these animals no regional inhomogeneities of flow and metabolism were present remote from the infarct. In contrast, in three animals cysts were located in the white matter, leading to pronounced hemodynamic and metabolic disturbances throughout the brain. It is concluded that edema-induced brain swelling was the main cause for reduction in blood flow and metabolism.

Surgical Procedure

tion, and sampling of arterial blood. Following tracheotomy, animals were immobilized and artificially ventilated. Arterial blood gases and arterial pH were controlled intermittently and, if necessary, adjusted to physiological levels by appropriate setting of the respiration pump and infusion of sodium bicarbonate. Body temperature was kept constant at 37°C.

Triple-labelled Autoradiography
Regional blood flow, glucose consumption and protein synthesis were measured in the same animal with \(^{131}\)I-iodo-antipyrine (specific activity 7.45 mCi/mg), \(^{14}C\)-2-deoxyglucose (specific activity 300–350 mCi/mmol) and a mixture of 5 tritiated amino acids (total activity 0.5 mCi/100g), respectively. The isotopes were purchased from NEN Chemicals, Dreieichhain, FRG. First, a bolus of \(^{14}C\)-2-deoxyglucose (10 mCi/100g) was given intravenously for determination of glucose consumption according to Sokoloff et al. Twenty-five minutes later \(^3\)H amino acids (0.5 mCi/100g) were injected intravenously for determination of protein synthesis according to Bodsch (in preparation) and 44 min after deoxyglucose application \(^{131}\)I-iodo-antipyrine was infused intravenously at a constant speed for 1 min for assessment of regional cerebral blood flow, as described by Sakurada et al. After tracer injections arterial blood samples were withdrawn for measuring specific amino acid radioactivity and for determination of the concentration of \(^{14}C\)-2-deoxyglucose, glucose and \(^{131}\)I-iodo-antipyrine; the time intervals chosen were as described in the original procedures. At the end of the \(^{131}\)I-iodo-antipyrine infusion the animals were decapitated into liquid nitrogen for rapid freezing of the brain.

Cryostat sections of 20 \(\mu\)m and \(^{131}\)iodine standards were immediately exposed for 24 hours on Kodak NMB film for recording of \(^{131}\)I-iodo-antipyrine radioactivity. At the same time radioactivity of arterial blood samples was measured and blood flow was calculated according to the equation by Sakurada et al. After \(^{131}\)I-iodo-antipyrine had decayed for 8 weeks, sections were again exposed with \(^{14}C\)-standards for 14 days on Kodak NMB film for recording of \(^{14}C\)-radioactivity. Plasma concentration of \(^{14}C\)-2-deoxyglucose and glucose was determined, and glucose consumption was calculated according to Sokoloff et al. Since brain hypoglycemia influencing the lumped constant \(^K\) was not detected in the brains examined (see below) glucose consumption was calculated using the lumped constant of control animals as described by Sokoloff et al. Finally, \(^{14}C\)-radioactivity and free \(^3\)H amino acids were removed from the section by washing it for 14 hours in a mixture of 10% trichloroacetic acid, 70% ethanol, 2% polyvinylpropolidone, 0.1% Nonidet-NP-40, and radioactivity of \(^3\)H amino acids incorporated into proteins was determined by exposure to tritium sensitive film for 3 weeks. Protein synthesis rate was quantified in small tissue samples (0.5 mg) taken from the block from which cryostat sections were cut. The procedure used is described elsewhere and includes the determination of specific radioactivity of free amino acids, of amino acids bound to tRNAs, and of protein-incorporated amino acids, using high performance liquid chromatography. The numbers obtained were used to calibrate the autoradiograms by plotting protein synthesis rate against optical density of the corresponding brain regions.

The degree of cross contamination of the three autoradiograms was tested by exposing sections with appropriate standards of all three isotopes, and was found to be negligible.

Serum Protein Extravasation
Regional serum protein extravasation was evaluated by means of immunooautoradiography as described elsewhere.

Imaging of Biochemical Substrates
The regional tissue content of ATP and glucose was estimated on freeze dried brain sections by means of substrate specific bioluminescence. \(^{12}\) \(^{14}\) Twenty \(\mu\)m cryostat sections were freeze dried and covered by 60 \(\mu\)m thick sections of frozen solutions containing all necessary enzymes, coenzymes and cofactors involved in the bioluminescent reactions. Bioluminescence light emission was recorded on photographic film (Agfa Pan, 25 or 100 ASA). NADH concentration of the tissue section was determined according to Welsh and Rieder by illuminating the tissue block with ultraviolet light and recording NADH fluorescence at 470 nm.

Image Processing
Autoradiograms and bioluminescent pictures were evaluated with an image processing system consisting of a rotating densitometer (Scandic 3, Joyce Loebl, Gateshead, United Kingdom), an image analyser (ID 22200 De Anza, Santa Clara, USA) and a laboratory computer (PDP 11/24, Digital Equipment, Maynard, USA). Areas of interest were identified, and quantitative data were calculated, using the appropriate operational equations (see above).

Results
Control measurements: regional cerebral blood flow, glucose consumption and protein biosynthesis were obtained in a group of 3 normotensive BD-IX rats which were submitted to the same anesthesia and the same surgical procedure as the experimental group. Cortical blood flow amounted to 1.34 ± 0.13 ml/g/min, glucose consumption to 0.40 ± 0.02 \(\mu\)mol/g/min and protein synthesis rate (amino acid equivalents incorporated into proteins) to 85 ± 9 \(\mu\)mol/g/min. Systemic arterial blood pressure during tracer application was 114.7 ± 19.2 mm Hg.

All 5 stroke-prone spontaneously hypertensive rats (SHR-SP) exhibited neurological symptoms before induction of anesthesia. The most prominent feature was a distinct reduction of spontaneous motor activity, combined with neglect of cleaning behaviour. In one animal spastic paresis of the left hindlimb and a marked weakness of the right hindlimb were present. Epileptic seizures were not observed. During 0.8% halothane anesthesia and after termination of the surgical procedure, arterial blood pressure was 126 ± 15.7
EDEMA-INDUCED BRAIN SWELLING IN SHR/Paschen et al

FIGURE 1. ATP-bioluminescence images of SHR-SP, representing regional cerebral ATP content in 5 individual animals. Note the high, homogenous bioluminescence in animals with cysts in the cerebral cortex (A, B) and the inhomogenously depressed bioluminescence in animals with edematous swollen white matter (C-E).

mm Hg. This value was not significantly higher than that of the normotensive control group, but lower than in the awake animals which in their home laboratory before shipment exhibited a blood pressure of more than 200 mm Hg.

Histological examination of the cryostat sections revealed structural alterations in all 5 animals, but the size and localization of these lesions varied considerably. Two different patterns could be distinguished (fig. 1): in two animals huge, sharply demarcated cysts were visible in the cortical grey matter, located near the borderzone between the anterior and middle cerebral arteries (fig. 1A, B). In the other 3 animals cysts were present in the deep cerebral white matter (fig. 1C-E). These animals exhibited severe cerebral edema as evidenced by massive swelling of perifocal white matter. In the cysts blood flow, glucose metabolism and protein synthesis had ceased, and ATP and NADH-fluorescence were absent (fig. 2, 3). Glucose-induced bioluminescence, however, persisted indicating high glucose content of the cystic fluid.

In the two animals exhibiting cortical lesions no regional inhomogeneities of flow, metabolism and biochemical substrates were present remote from the lesion (fig. 2). The content of glucose and ATP was high, glucose consumption and protein synthesis were similar to that found in normotensive control animals (table 1). There was, however, a slight decrease of cortical blood flow. The demarcation of the lesions was sharp, and there was no rim of hyperemia or hypermetabolism, as previously observed in acute infarcts. 20, 21

In the animals with white matter lesions, in contrast, pronounced disturbances were present throughout the brain (fig. 3). Blood flow, glucose metabolism, and the content of ATP were markedly and inhomogeneously depressed, particularly in the edematous white matter. In contrast, protein synthesis within the cerebral cortex was similar to that found in normotensive control animals (table 1). Glucose content was only slightly decreased (fig. 3E), indicating that depression of metabolism was not caused by insufficient glucose supply to the edematous tissue.

Inhibition of glucose metabolism correlated with the severity of brain swelling: in the brain of the animal exhibiting the most severe degree of brain swelling (fig. 1E) glucose metabolism was also most markedly reduced and amounted only to 30% of that of the normotensive control group.

Discussion

The strain of stroke-prone spontaneously hypertensive rats (SHR-SP) is a generally accepted model of cerebral infarction induced by chronic hypertension. In these animals hypertension leads to atherosclerotic alterations of the cerebrovascular system 20 with ring-
like fat deposits in the circle of Willis
and fibrinoid necrosis of the wall of intracerebral arterioles. The lesions are located mainly in the borderzones of the supplying arteries, indicating the importance of hemodynamic factors for the pathological process. This is also reflected by markedly reduced cerebral blood flow which can be improved by antihypertensive treatment.

In SHR-SP, mean arterial blood pressure rises above 200 mm Hg as a consequence of genetic predisposition in combination with a special salt-rich diet. In the rats used for the present investigation, average blood pressure amounted to only 126 mm Hg. This reduction was caused either by the transport or, more likely, by halothane anesthesia used during the surgical preparation. Although blood pressure was still within the autoregulatory range of SHR-SP, a reduction of cerebral blood flow cannot be excluded. The flow measurements obtained, however, did not differ from previously reported values, and we therefore consider the present observations as representative for the normal hemodynamic state of these animals.

Previous morphological studies have revealed that infarcts in SHR-SP are mainly located in the cerebral cortex, whereas basal ganglia and thalamus are less frequently involved. Infarcts may lead to secondary lesions such as widespread rarefaction and cyst formation. In the present series of 5 experiments, only 2 animals exhibited this type of lesion. In the other 3 animals infarcts were located in the deep cerebral white matter. This difference of localization was associated with a different metabolic pattern. In animals with cortical defects glucose utilization and cerebral blood flow were normal or only slightly reduced and there were no inhomogeneities of either blood flow or metabolism. When infarcts were located in the white matter, on the other hand, considerable brain swelling occurred with gross reductions of blood flow, glucose utilization, and ATP content throughout the whole brain. Only glucose content remained normal, indicating that the metabolic disturbances were not due to a reduction of glucose availability.

The different metabolic pattern correlated clearly with the degree of edema development. Cerebral infarcts are associated with permeability disturbances of the blood-brain barrier causing extravasation of serum proteins. The break-down of the barrier does not depend on the localization of the lesion, but the spread of edema is much faster and more extensive in the white matter than in the cortex. The reason is the geometrical configuration of the extracellular channels which in the white matter are arranged in parallel, whereas in the cortex they form a complex tortuous network. It is, therefore, not surprising that in the present investigation white matter lesions caused more pronounced edema and were associated with more severe metabolic disturbances than lesions of the same size located in the cerebral cortex. This observation is in line with numerous earlier reports which also stress the preferential formation of vasogenic edema in the white matter (for review see Baethmann).

An alternative explanation of the two different pathobiocchemical patterns would be that these changes represent two different time points of the same pathophysiological process. However, this explanation is unlikely because it is not conceivable that either the grey matter or the white matter lesions are reversible at a later stage.

The combination of reduced blood flow, glucose utilization and ATP in the presence of normal glucose metabolism. When infarcts were located in the white matter, on the other hand, considerable brain swelling occurred with gross reductions of blood flow, glucose utilization, and ATP content throughout the whole brain. Only glucose content remained normal, indicating that the metabolic disturbances were not due to a reduction of glucose availability.

content, as observed in the edematous brain tissue of animals with white matter lesions, is on the first sight difficult to interpret. Reduced blood flow in the presence of normal tissue glucose content should lead to activation of anaerobic glycolysis, as has been previously observed in other conditions of mild ischemia. 27, 28 The low glucose utilization in the present experiments, therefore, must have another reason. One explanation could be that prolonged state of brain edema causes inhibition of glycolytic activity despite continuing glucose supply. Such disturbances have, in fact, been previously observed in brain regions reperfused after prolonged state of cerebral ischemia. 29 Another explanation is the partial volume effect of edematous tissue. White matter edema around infarcts is of the vasogenic type. 23 It therefore can be expected to reduce the blood-brain barrier to protein passage. The actual decrease in the intracellular compartment. Since glucose utilization and ATP production are intracellular events, total tissue content of these substrates may decrease without any change of intracellular concentration. Such an effect does not apply to glucose content because glucose is distributed both extra- and intracellularly. The actual decrease of metabolic activity, therefore, is less severe than it appears on the here presented images. However, even with appropriate corrections made, perifocal edema remains a major complicating factor for metabolic disturbances following stroke, and therefore should be a main target for therapeutic interference.
