Role of Carotid Stenosis in Ischemic Stroke

Chang Z. Zhu, MD, and John W. Norris, MD

Using Doppler ultrasonography, we evaluated the frequency and severity of carotid artery stenosis in 261 patients with carotid ischemic strokes, 813 patients with carotid transient ischemic attacks, 500 patients with asymptomatic neck bruits, and 500 controls. Most patients with strokes and transient ischemic attacks had no associated carotid artery disease (55% and 64%, respectively), and such patients without neck bruits were even more likely to be without carotid artery disease (69% and 77%, respectively). Carotid stenosis was more frequent and more likely to be severe in symptomatic than in asymptomatic patients (p < 0.0002), even after adjusting for age and sex. Carotid stenosis is present in only a minority of patients with strokes and transient ischemic attacks, especially if neck bruits are absent, and the cause of the ischemic cerebral events in most of these patients remains unexplained. (Stroke 1990;21:1131-1134)

Carotid ischemic stroke is commonly attributed to atherosclerosis of the extracranial carotid arteries, with subsequent embolic or hemodynamic cerebral ischemia.1,2 However, data from stroke registers indicate that even after accounting for all carotid and cardiac disease, the etiology in most cases remains unexplained.3

Neck bruits are commonly associated with underlying extracranial carotid artery disease and therefore are associated with an increased risk of stroke.4,5 Although community studies of patients with neck bruits indicated that subsequent strokes were unrelated to the side of the bruit,6,7 later reports including data on noninvasive carotid imaging with clinical follow-up suggest that the more severely stenosed carotid artery, which does not necessarily correspond to the side of the neck bruit, carries the greater stroke risk.5,8 We previously evaluated the frequency of carotid stenosis in 336 patients with asymptomatic neck bruits and found that 61% had ipsilateral and 28% had contralateral carotid artery stenosis.9 We also have investigated the laterality of ischemic cerebral events during follow-up in patients with asymptomatic carotid stenosis and found that 80% of the events occurred ipsilateral to the more stenosed artery; in symptomatic patients, this number was 72%.10 Risk of stroke therefore relates to both the presence of neck bruits and to the underlying carotid lesion, but the relation is still uncertain.

We compared the frequencies of neck bruits and carotid stenosis (determined by Doppler imaging) in asymptomatic patients with the frequencies in patients with transient ischemic attacks (TIAs) and ischemic strokes to determine the role of carotid artery disease in subsequent cerebral ischemic events.

Subjects and Methods

Data were collected between July 1982 and July 1986. The two symptomatic groups comprised 261 consecutive patients admitted with carotid ischemic stroke (in whom carotid Doppler ultrasonography is routinely performed) and 813 patients with carotid TIAs referred to our Doppler laboratory. Patients with vertebrobasilar TIAs were excluded. The two symptomatic groups were divided in subgroups of patients with and without neck bruits. The asymptomatic group consisted of 500 patients referred to our Doppler laboratory with asymptomatic neck bruits. A control group of 500 patients without neck bruits referred to the same vascular laboratory with nonvascular diagnoses had epilepsy, headache, or dizzy attacks.

Neck bruits are recorded in all patients referred to our Doppler laboratory after auscultation by a trained technician or the reporting physician. A previous comparison in our laboratory of the accuracy and consistency of neck bruit auscultation indicated a high concordance among observers.9

The diagnoses of stroke were all made by referring neurologists from the admitting hospitals. The diagnoses of TIAs were screened by the neurologist or neurological fellow attending the Doppler laboratory. Patients with insufficient evidence or, in our opinion, incorrect diagnoses of TIAs were excluded.

Carotid Doppler ultrasonography was performed in all patients with the continuous-wave method (Model 1050, Carolina Medical Electronics, Inc., King, N.C.) without B-mode imaging. We previously documented the accuracy, sensitivity, and specificity of this tech-

Bruits refer to neck bruits only. Moderate stenosis, 35–75% diameter reduction (4–10 KHz); severe stenosis, >75% diameter reduction (11–20 KHz); TIA, transient ischemic attacks.

*p<0.01, 0.025, respectively, different from TIA by $x^2$ test.

$\ddagger$p<0.001 different from without bruit by $x^2$ test.

$\ddagger\ddagger$p<0.0002 different from asymptomatic by analysis of variance, adjusting for sex and age.

FIGURE 1. Frequency and severity of carotid artery stenosis in symptomatic and asymptomatic patient groups. Dotted areas, 35–75% stenosis; shaded areas, >75% stenosis.

of stroke in patients with atrial fibrillation implies a more important role for cardiogenic embolism than previously believed. At least 15% of ischemic strokes are documented to be due to cardiac disease, not only mural thrombosis, but also ventricular aneurysm, hypertension, and dilated cardiomyopathy. The real percentage is clearly much larger. Present laboratory methods for detecting potential cardiac sources of emboli are still imprecise, but they are improving.

There was a significant difference in the severity of carotid stenosis among the patients with neck bruits by group. This was not due simply to differing sex ratios or mean ages among the groups and therefore must indicate that more severe carotid artery disease relates directly to more severe cerebral ischemic disease.

Our finding that only 1.2% of controls had severe stenosis is similar to that of other community studies, and carotid artery disease is clearly uncommon in the asymptomatic population. For instance, screening 348 unselected volunteers at a "health fair" using a clinical questionnaire and carotid Doppler ultrasonography, Colgan et al found that only 5% of patients over age 60 years had any detectable carotid stenosis and that only 1–3% had stenosis of >80% diameter reduction. Two similar studies revealed detectable carotid artery disease in 5% and 5.9% of normal populations.

Carotid stenosis is clearly not a major cause of cerebral ischemia, especially in patients without neck bruits. Rational therapy for stroke cannot be instituted until the cause or causes of stroke are determined in this large population with unexplained cryptogenic stroke.

3. Sacco RL, Ellenberg JH, Mohr JP, Tatemichi TK, Hennerici MG, Rautenberg W, Mohr S: Stroke risk from carotid stenosis detected by carotid Doppler ultrasonography, but carotid stenosis was present in only a minority of those without neck bruits, so the causes of their strokes and TIAs remain unexplained. Cardiac investigations, such as echocardiography, were not performed systematically in these patients so we cannot comment on the frequency of cardioembolism. Our data support the observations made in stroke data banks: our understanding of the basic mechanisms of stroke is still grossly deficient. Mohr appropriately dubbed this idiopathic entity "cryptogenic stroke.

Since the carotid Doppler technique in our laboratory is inaccurate in diagnosing stenoses of <35% diameter reduction, nonstenosing or only mildly stenosing carotid sources of potential emboli might escape detection. However, although nonstenosing carotid ulcers may occasionally cause cerebral embolism, this point remains controversial, and if it occurs it must be unusual. Also, in studies in which stroke risk is correlated with the degree of carotid stenosis, lesions of <50% diameter reduction carry a very low risk of stroke. Therefore, even if minor degrees of carotid stenosis account for a few cases of cryptogenic stroke, they are unlikely to explain the majority.

Information from the National Institute of Neurological and Communicative Disorders and Stroke stroke data bank indicates that after neurologic investigation, approximately 22% of strokes can be attributed to carotid artery disease while 11.6% are considered lacunar; embolism of uncertain origin is the commonest cause of stroke. Recent advances in cardiac imaging, such as the "bubble" echocardiographic technique for detecting a patent foramen ovale, demonstrate that cardioembolic stroke from paradoxical sources is not uncommon. The recent introduction of transesophageal echocardiography reveals cardiac sources of emboli missed by standard echocardiographic techniques. Also, the high risk of stroke in patients with atrial fibrillation implies a more important role for cardiogenic embolism than previously believed. At least 15% of ischemic strokes are documented to be due to cardiac disease, not only mural thrombosis, but also ventricular aneurysm, hypertension, and dilated cardiomyopathy. The real percentage is clearly much larger. Present laboratory methods for detecting potential cardiac sources of emboli are still imprecise, but they are improving.
