Effect of Flunarizine on Electroencephalogram Recovery and Brain Temperature in Gerbils After Brain Ischemia

Stanley L. Cohan, MD, PhD; David Redmond; and Mei Chen, MD

Background and Purpose: This study was designed to determine whether flunarizine enhances the rate of brain recovery as measured by electroencephalography after cerebral ischemia and whether these effects are attributable to changes in brain temperature.

Methods: Male gerbils (n=81) were treated with either 10 mg/kg flunarizine or its vehicle, β-cyclodextrin, intraperitoneally, 60 minutes before bilateral carotid occlusion of either 4 or 6 minutes' duration. The electroencephalogram was continuously recorded in the preischemic, ischemic, and postischemic stages of the experiment and rated for the time necessary for the return of 4-6, 7-10, and 11-15 Hz activity. In a second set of experiments, intracerebral temperature was monitored for 60 minutes before ischemia, during 10 minutes of carotid occlusion, and for 60 minutes after ischemia.

Results: Flunarizine pretreatment resulted in significantly more rapid return of electroencephalographic activity in each of the three frequency categories monitored when compared with those animals pretreated with vehicle alone (p<0.001). Flunarizine had no effect on brain temperature before, during, or up to 60 minutes after termination of ischemia.

Conclusions: Flunarizine, which has been of efficacy in reducing neuronal death, mortality, and functional impairment when administered after ischemic insults, may have prophylactic value in accelerating brain recovery from ischemia, but does not have this effect as a result of altered brain temperature. (Stroke 1992;23:229-233)
transcutaneous oximeter (Nellcor). Temperature, MAP, and \( \text{O}_2 \) Sat were stabilized during a 10- to 20-minute period before onset of ischemia and recorded every 60 seconds before, during, and after termination of ischemia. Ischemia was produced by suspending a 24-g weight from the bifurcation of the carotid polypropylene loop. Adequacy of the occlusion was verified by direct inspection of the carotids, and, in the time of onset, by isoelectric EEG. Gerbils were subjected either to 4 minutes (group 1, \( n=40 \)) or 6 minutes (group 2, \( n=48 \)) of ischemia. For an animal to be included in the final data, an isoelectric EEG had to be achieved within 15 seconds after carotid occlusion. Following release of the occlusion, each gerbil remained anesthetized in the postischemic period, with rectal temperature maintained at 37°C until EEG recovery had taken place. We have divided the preischemic anesthetized gerbil EEG into three rhythm frequency categories: 4–6, 7–10, and 11–15 Hz electric activity, respectively. The EEG frequencies were determined by two methods. The EEG tracings were made on paper printed in 1-mm increments, and by knowing the speed of the paper drive (50 mm/sec), one could calculate the frequency of the EEG waveforms. The EEG frequencies were also measured using electrocardiogram calipers set at the bases of both arms of the deflection of each measured wave. The caliper was then transferred to a premeasured grid from 1 to 20 Hz to make a direct reading. If the calipers fell between two frequencies, the measurement was assigned to the higher of the frequencies. In no case was there a discrepancy between the results of the two methods of measurement. One hour before onset of ischemia, gerbils received a single intraperitoneal injection of flunarizine dissolved in 10 mg/kg hydroxypropyl \( \beta \)-cyclodextrin (Janssen Pharmaceutica, Beerse, Belgium) or the cyclodextrin vehicle alone. One investigator analyzed the EEGs without knowledge of whether animals had received flunarizine or vehicle alone.

An additional group of male gerbils, also weighing 65–75 g, were prepared in the identical manner to those above except that instead of EEG leads, a wire thermal probe (Omega Hyp-O) was inserted into the right striatum, through a hole made in the skull with a 20-gauge cutting needle, and attached to a meter (Omega 67OT) capable of measuring temperature in 0.1°C increments. Both the rectal probe and the intracerebral rectal probe were calibrated against a United States Bureau of Standards-approved mercury thermometer in a water bath over a temperature range of 28–40°C. Each animal's head was held in a small animal stereotactic apparatus (Konte) and the probe held in place by attachment to an adjustable bar mounted on the stereotactic apparatus. One hour prior to onset of ischemia, gerbils received a single intraperitoneal injection of flunarizine dissolved in 10 mg/kg hydroxypropyl \( \beta \)-cyclodextrin or the cyclodextrin vehicle alone.

The intracerebral position of the thermal probe was verified by autopsy after termination of the experiment. Ambient temperature in the laboratory was 20±1.0°C throughout these experiments and rectal temperature of the gerbils maintained at 37±0.2°C by the aforementioned heating blanket. Brain and rectal temperature were continuously monitored and recorded every 60 seconds for 20 minutes before and 60 minutes after intraperitoneal administration of either 10 mg/kg flunarizine or cyclodextrin vehicle, following which bilateral carotid occlusion was performed, as described above, for 10 minutes. Brain and rectal temperature were continuously monitored and recorded each minute during the 10 minutes of cerebral ischemia and for 60 minutes after termination of the ischemia.

Differences in the mean time necessary for return of activity at 4–5 Hz, 7–10 Hz, and 11–15 Hz in the postischemic period in flunarizine versus vehicle-pretreated groups were analyzed by the Levene statistic, which revealed a failure to meet parametric assumption of homogeneity of variance. Therefore, comparison of means for significant differences were achieved by the Mann-Whitney U test. Differences in mean brain temperatures in flunarizine- and cyclodextrin-treated controls were analyzed for significance by the \( t \) test because use of the Levene statistic revealed that the data met the parametric assumption of homogeneity of variance.

Results

The EEG failed to become isoelectric in two flunarizine-pretreated gerbils in group 1 and in one vehicle-pretreated and two flunarizine-pretreated gerbils in group 2. In two additional flunarizine-pretreated gerbils in group 2, suspension of the 24-g weight tore the carotid arteries and led to rapid exsanguination. These animals were excluded from the analysis of data. In all other gerbils, the EEG became isoelectric within 15 seconds after carotid occlusion. There were no significant differences in rectal temperatures, MABP, or \( \text{O}_2 \) Sat before, during, or after cessation of ischemia between the different groups (Table 1) and no significant differences in the time of onset of isoelectric EEG in the different groups (Table 2). Pretreatment with 10 mg/kg i.p. flunarizine resulted in significantly more rapid recovery of EEG activities (\( p<0.001 \)) after either 4 or 6 minutes of ischemia than that observed in vehicle-treated animals (Table 2B). Time of onset of ischemia was measured from time of carotid occlusion and not from the time of onset of isoelectric EEG. In both vehicle- and flunarizine-treated gerbils, 4–5 Hz activity was the first to reappear and 11–15 Hz activity reappeared last. During the recovery phase, paroxysmal bursts, which did not appear epileptiform, were occasionally seen on EEG in vehicle- but not flunarizine-treated animals. No clinical seizures were observed before, during, or after cessation of ischemia during the period of EEG monitoring.

In animals whose brain temperature was measured, there were no significant differences in vehi-

cle- and flunarizine-treated groups before (Figure 1A), or after receiving vehicle or flunarizine (Figure 1B), during forebrain ischemia (Figure 1C), or in the 60-minute postischemic period (Figure 1D).

Discussion

The results of these studies suggest that flunarizine enhances the rate of recovery of the brain from ischemia as measured by return of spontaneous electrical activity on EEG recording. We did not attempt to determine the time necessary for the EEG to return to normal in the postischemic period because we do not believe that the gerbil EEG is sufficiently characterized to accurately define such an end point by visual inspection of the tracing; instead, we measured the time required, after cessation of ischemia, for the reappearance of 4–5 Hz, 7–10 Hz, and 11–15 Hz activity. Quantitative spectrum analysis, which was not available to us, might be used to determine when the EEG returns to normal. Using quantitative analysis, Wauquier et al13 have demonstrated improved EEG recovery following global ischemia in the dog. Flunarizine administration has also produced generalized slowing in EEG background activity in human subjects with epilepsy,14 power spectrum analysis demonstrating a reduction in the alpha/theta ratio. We are unaware of similar analysis of flunarizine effects on control nonepileptic subjects. In comparing the preischemic EEG of flunarizine- and cyclodextrin-treated controls, we could detect no differences between the two groups by visual inspection. However, because our study was designed to detect the time of reappearance of EEG frequencies rather than the relative abundance of various frequencies, we believe this to be a relatively minor shortcoming of our study.

Although flunarizine treatment either before or after ischemic insult to the brain reduces neuronal damage as viewed histologically,5,8–10 prolongs animal survival,11 and enhances functional recovery,12 its

pharmacological mechanisms of action are not well understood. Flunarizine does inhibit calcium-stimulated vasoconstriction, and may increase cerebral blood flow, the prevention of postischemic fall in cerebral blood flow being a potential protective mechanism of action. Calcium overload is an important potential mechanism of postischemic neuronal damage, and increased intraneuronal calcium has been observed ultrastructurally immediately after cessation of global cerebral ischemia. Flunarizine inhibits calcium conductance through T- and L-type voltage-regulated channels in cardiac muscle, inhibits calcium conductance through T-type channels in rat hypothalamic neurons, blocks presynaptic calcium uptake after sustained in vitro depolarization, and also delays anoxia-induced neuronal depolarization. Flunarizine acts as a calcium antagonist, but probably has other modes of action as well, particularly as a sodium antagonist. Thus, flunarizine prevents calcium-dependent sodium ionophore-induced cell death, probably in part due to its role as a calcium antagonist, but also possibly as a result of sodium antagonist activity. Additional direct evidence that flunarizine is a sodium antagonist is that it can block a low-threshold tetrodotoxin (a sodium-channel blocker)-sensitive channel. Although no specific neuronal receptor site for flunarizine has been identified, it is highly lipophilic and strongly bound to intracellular phospholipid residues, particularly phosphatidyl serine, and in so doing may effect membrane fluidity, reducing the likelihood of opening of intramembranous ion channels and thus impeding potentially damaging ionic flux following anoxia or ischemia. Flunarizine's effects on postischemic ionic flux and on ischemia-induced depolarization may in part explain its use resulting in the more rapid return of EEG activity seen in our animals during the postischemic period.

We administered flunarizine intraperitoneally 1 hour before ischemia because a previous study demonstrated that we would achieve maximum levels of 2 µg flunarizine/g brain 45–60 minutes after intraperitoneal injection.

The onset of an isoelectric EEG within 15 seconds after bilateral carotid ligation is similar to the observations of others using a similar model of gerbil ischemia. Although clinical seizure activity is frequently seen after cerebral ischemia in the gerbil, we noted no clinical seizures or epileptiform discharges on EEG. This may in part be the result of the shorter duration of ischemia used in this study. We have observed clinical seizures within 1 hour postischemia in 100% of gerbils from the same animal colony when they were subjected to 20 minutes of bilateral carotid occlusion. An additional reason we may not have observed seizures is that the animals remained anesthetized in the postischemic period, in some cases up to 60 minutes.

Although we maintained body temperature via a rectal probe controlled heating blanket, the large surface area to volume ratio of a small rodent could lead to variations in head temperature which could significantly affect outcome. Not only may reduced brain temperature enhance postischemic neuronal survival, but a potential mechanism of pharmacological efficacy of some compounds in the treatment of brain ischemia may be their production of sustained hypothermia. Our temperature monitoring results fail to demonstrate significant variations in brain or rectal temperatures using our thermal blanket set-ups before, during, or after ischemia. Furthermore, flunarizine at the dose we used had no significant effect before, during, or after forebrain ischemia. The 10-minute duration of ischemia in the brain temperature experiments exceeded the duration of ischemia (4 or 6 minutes) in the EEG recovery studies to demonstrate that in ischemic periods inclusive of, and even exceeding, those used in the postischemic EEG recovery experiments, flunarizine had no significant effect on brain temperature during or after termination of ischemia. These results demonstrate that flunarizine's effects on EEG recovery are not the result of drug-induced alteration in brain temperature in the intras ischemic period at least up to the first 60 minutes of the postischemic period. We chose to measure intracerebral temperature rather than scalp temperature because we wanted to determine flunarizine's effects on brain temperature, and there may be significant variation between scalp and brain temperature. There was an almost 2°C difference between brain and rectal temperatures in our animals even before drug administration or onset of ischemia. Differences in accuracy of the temperature probes would not explain these differences in temperature because the accuracy of both the rectal and brain probes were verified by a US Bureau of Standards–approved thermometer.
