Concomitants of Asymptomatic Retinal Cholesterol Emboli

Askiel Bruno, MD; Patrick W. Russell, DO; William L. Jones, OD; Jeffrey K. Austin, OD; Eric S. Weinstein, MD; and Susan R. Steel, RN, BSN

**Background and Purpose:** Asymptomatic retinal cholesterol emboli are sometimes encountered on ophthalmoscopic examination. They are associated with decreased survival, but their clinical significance is not fully known. We sought to determine which vascular risk factors are associated with such emboli.

**Methods:** We studied 70 consecutive men (55–84 years old) with asymptomatic retinal cholesterol emboli diagnosed in an eye clinic. Twenty-one men (57–78 years old) from the same eye clinic without retinal emboli or retinal ischemic events were randomly selected as control subjects. We determined vascular risk factors, presence of ischemic heart disease, and extracranial carotid artery disease.

**Results:** Patients had a higher prevalence of hypertension, smoked more, and had a higher prevalence of heterogeneous or echolucent carotid plaques on either side than did control subjects (p<0.001 for all three factors). Patients also had a higher prevalence of carotid artery stenosis ≥50% on either side and a higher prevalence of ischemic heart disease than did control subjects, but these did not reach statistical significance (p=0.06 and p=0.08, respectively).

**Conclusions:** Our findings suggest that hypertension and cigarette smoking may be important in the pathogenesis of asymptomatic retinal cholesterol emboli and that these emboli indicate systemic atherosclerosis rather than ipsilateral carotid artery stenosis. (Stroke 1992;23:900–902)

**Key Words** • embolism • retina • risk factors

Retinal cholesterol emboli are usually attributed to an atherosclerotic plaque at the common carotid artery bifurcation. These emboli can be symptomatic or asymptomatic. The relationship between asymptomatic retinal cholesterol emboli, vascular risk factors, and extracranial carotid artery stenosis has not been recently studied with the use of modern diagnostic tools. Better understanding of the factors which predispose to asymptomatic retinal cholesterol emboli may lead to a more effective prevention of vascular complications in these patients. To identify the concomitants of asymptomatic retinal cholesterol emboli we studied 70 patients and 21 control subjects.

**Subjects and Methods**

Between January 1989 and February 1991, we identified 70 consecutive patients with asymptomatic retinal cholesterol emboli among all patients examined in the Eye Clinic of the Albuquerque Veterans Affairs Medical Center and entered them into this study. This clinic had approximately 4,500 patient visits annually that included dilated ophthalmoscopic examination during this study. A retinal cholesterol embolus was diagnosed when an orange-, yellow-, or copper-colored fragment was seen in a retinal arteriole. An embolus was considered asymptomatic if the patient denied sudden monocular visual loss and had no monocular visual field loss on examination. Patients with symptomatic retinal emboli were excluded. Twenty-one patients of similar age without retinal emboli or ischemic ocular symptoms who were being seen in the same eye clinic during this study were randomly asked to participate as controls. All subjects were men. Patients were 55–84 (mean, 69) years old, and control subjects were 57–78 (mean, 68) years old. The reasons that patients came to the eye clinic on the day the retinal cholesterol embolus was found were as follows: for refraction, 16 patients; cataract, 15; various retinal degenerative disorders, 9; to rule out diabetic retinopathy, 8; to follow up diabetic retinopathy, 6; to follow up or rule out ocular hypertension, 4; to follow up or rule out glaucoma, 4; ocular discomfort, 3; to follow up branch retinal vein occlusion, 2; contralateral transient monocular visual loss, 1; visual fields testing after stroke, 1; and abducens nerve paresis, 1. The reasons that control subjects came to the eye clinic on the day they entered this study were as follows: cataract, 5 patients; to follow up or rule out ocular hypertension, 3; to follow up or rule out glaucoma, 3; to rule out diabetic retinopathy, 3; to follow up diabetic retinopathy, 2; refraction, 2; macular degeneration, 1; conjunctivitis, 1; and nonspecific visual disturbance, 1.

Results

Results are summarized in Table 1. Carotid artery stenosis $\geq 50\%$ ipsilateral to the embolus was found in 7 of 56 patients (13%); six of the patients had $50-79\%$ stenosis, and one had occlusion. Carotid artery stenosis $\geq 50\%$ contralateral to the embolus was found in 5 of 56 patients (9%); three of the patients had $50-79\%$ stenosis, and two had occlusion. One of the patients had bilateral $50-79\%$ carotid stenosis. All control subjects had $<50\%$ carotid stenosis on either side.

Discussion

In 1961 Hollenhorst described orange-, yellow-, or copper-colored fragments seen at retinal arteriolar bifurcations in 31 of 228 patients with occlusive cerebrovascular disease; he suggested that these were cholesterol crystals arising from ulcerated atherosclerotic lesions of the cardiac valves, aorta, or the carotid arteries. In 1963 David et al examined similar bright plaques from the eye of a patient with a fatal ipsilateral cerebral infarct after surgical manipulation of the ipsilateral carotid artery. The plaques were composed of doubly refractile cholesterol ester crystals whose histochemical and optical characteristics were identical to those found in the patient's carotid artery atheroma and middle cerebral artery embolus. Others have also suggested that retinal cholesterol emboli arise from carotid atherosclerotic plaques.

Among Hollenhorst's initial 31 patients with retinal cholesterol emboli, 21 (68%) were asymptomatic; of the 208 patients reported subsequently, 175 (84%) were asymptomatic. Most retinal cholesterol emboli are asymptomatic, probably because of their flat shape. When these flat cholesterol crystals lodge in a retinal arteriole, they usually do not produce an occlusion unless they are associated with a thrombus.

Arterial hypertension is a well-known vascular risk factor. Hollenhorst found hypertension in 70% of his 208 patients with retinal cholesterol emboli. The prevalence of hypertension in our patients was similar (78%) and was significantly higher than in control subjects (33%, $p < 0.001$), which suggests that hypertension may contribute to the pathogenesis of asymptomatic retinal cholesterol emboli. Most likely, hypertension enhances atherosclerosis, which predisposes an individual to cholesterol embolization.

Cigarette smoking is also a known vascular risk factor. The duration of cigarette smoking correlates with the severity of extracranial carotid atherosclerosis. In the Framingham study, the quantity of cigarettes smoked correlated directly with the risk of stroke. In our study, patients smoked significantly more than control subjects. This suggests that smoking may also contribute to the pathogenesis of asymptomatic retinal cholesterol emboli, probably by promoting atherosclerosis.

Diabetes mellitus and hypercholesterolemia are also known vascular risk factors. Among Hollenhorst's 208 patients, diabetes mellitus was present in 21%, and hypercholesterolemia (serum cholesterol $>250$ mg/dl) was also present in 21% (29 of 136 patients tested).
The prevalence of these vascular risk factors in our patients is similar and not significantly different from that in our control subjects. Diabetes mellitus and hypercholesterolemia do not appear to play an important role in the pathogenesis of asymptomatic retinal cholesterol emboli.

The prevalence of ischemic heart disease in our patients is similar to that in Hollenhorst's 208 patients (58% and 59%, respectively). Although in our study this is not significantly different from the prevalence in control subjects, there appears to be a trend toward an association between asymptomatic retinal cholesterol emboli and ischemic heart disease (p=0.08; Table 1).

Attention has focused on extracranial carotid atherosclerosis in patients with retinal cholesterol emboli. It has been suggested that retinal cholesterol emboli indicate an unstable carotid atherosclerotic plaque.1-7 Although asymptomatic retinal cholesterol emboli have been documented after carotid manipulation,2 arteriography,3 and carotid endarterectomy,4,6 in previous reports the carotid arteries were not studied systematically. In our study, the prevalence of carotid stenosis ≥50% ipsilateral to the embolus is relatively low in patients (13%) and not significantly different from that in control subjects (Table 1). However, carotid stenosis ≥50% on either side is more common in patients than control subjects and is nearly statistically significant (p=0.06; Table 1).

In contrast to the degree of stenosis, carotid plaque morphology is significantly different between patients and control subjects. Patients have a higher prevalence of heterogeneous or echolucent plaques on either side than do control subjects (p<0.001; Table 1). Carotid plaque morphology determined by ultrasound imaging correlates with plaque pathology15,16 and ischemic symptoms.13-19 Heterogeneous echogenicity or echolucency of a carotid plaque correlates with intraplaque hemorrhage and ischemic symptoms, whereas homogenous medium-to-high echogenicity correlates with fibrotic, collagenous, or fibrocalcific plaque and no ischemic symptoms. Asymptomatic retinal cholesterol emboli may be a presymptomatic manifestation of heterogeneous or echolucent carotid plaques. The high prevalence of bilateral heterogeneous or echolucent carotid plaques among patients (47%) suggests systemic atherosclerosis in addition to carotid artery disease ipsilateral to the cholesterol embolus.

Our study demonstrates that asymptomatic retinal cholesterol emboli are associated with hypertension, cigarette smoking, and presence of a heterogeneous or echolucent carotid plaque on ultrasound. Carotid studies and the prevalence of ischemic heart disease suggest that asymptomatic retinal cholesterol emboli reflect systemic atherosclerosis and not ipsilateral carotid artery stenosis ≥50%. Extracranial carotid artery plaque is a likely source of asymptomatic retinal cholesterol emboli, but the main source has not been proven. Whether such emboli are an independent risk factor for symptomatic cerebrovascular and cardiovascular disease, and how serious a risk, remains to be determined.
