Background and Purpose

Vasomotor changes occur in the arm after paralytic stroke. Previous studies have provided conflicting results, with most showing an increase in skin temperature of the hemiplegic arm. However, a number of patients complain of distressing coldness of the hemiplegic arm.

Methods

Eleven patients with symptomatic coldness and 10 patients with hemiplegia but no coldness were recruited. The severity of the symptom of coldness was compared after questionnaire with other common symptoms after stroke. A thermographic camera was used to record the skin temperature response to cold stress. Blood flow to both hands was also measured simultaneously by means of two plethysmographies. In all patients there were no symptoms in the unaffected arm, and this was used as a control.

Results

The symptom of coldness rated highly compared with other symptoms. In the symptomatic group the finger temperature on the hemiplegic side was lower at rest (median difference at rest, 0.65°C; P<0.001) and at all times after cold stress. In the asymptomatic group the fingers on the hemiplegic side were colder at rest and after initial cooling (median temperature difference, 0.2°C) but at no other time. Hand blood flow on the hemiplegic side was also decreased in the symptomatic group by 35%. This was not seen in the asymptomatic group.

Conclusions

Coldness of the hand may be a severe and distressing symptom in some patients after hemiplegia. Symptomatic patients have lower finger skin temperatures at rest and after standard cold stress. These symptomatic patients also had reduced blood flow to the hemiplegic hand. (Stroke. 1994;25:1765-1770.)

Key Words: • hemiplegia • thermography • vasomotor system

Subjects and Methods

Stroke patients were recruited from the clinics and wards at Seacroft and St James' hospitals and stroke clubs in Leeds. No attempt was made to define a sample frame because we were studying a clinical phenomenon rather than performing an epidemiological survey. Eligible patients were those with unilateral weakness with or without the symptom of coldness in the affected arm. Patients with severe dysphasia or with spasticity resulting in an inability to open the hand fully were excluded.

All patients gave informed consent to participate in the trial, and approval for the trial was obtained from the local ethics committee.

An initial assessment consisted of a questionnaire asking about the presence and severity of symptoms in the arms. A scale of 0 to 5 was used to quantify feelings of coldness as well as heat, pain, pins and needles, and numbness in the arm. The limits of the scale were 0 (no symptoms) to 5 (very severe). This rating scale was performed to compare the subjective severity of the symptom of coldness compared with some other common symptoms after stroke. Motor power was assessed in each patient with the motoricity index. This involved power testing of various movements. In the upper limb pinch grip, elbow flexion, and shoulder abduction were tested. In the lower limb ankle dorsiflexion, knee extension, and hip flexion were tested. The motoricity index has been validated as a measure of motor function after stroke. The maximum score attainable is 100, and when interpreting the score a higher value represents greater motor power.

We used two methods to measure different aspects of the circulation in the hands. A thermographic camera was used to determine resting skin temperature in the fingers and the response to local cooling and subsequent rewarming. Venous occlusion plethysmography was used to measure the total blood flow to the hands at a neutral temperature and after cooling. We also performed plethysmography on 6 age-matched healthy control subjects who were taking no vasoc-
The page contains a table and a graph related to the study of stroke patients with and without cold hemiplegic arms. The table compares characteristics of stroke patients with and without cold hemiplegic arms, including age, sex, hemiplegic side, time since stroke, motoricity score, and smokers. The graph illustrates the median finger temperature in each hand during the cold stress test in patients complaining of cold in the hemiplegic hand. The results are presented in terms of mean symptom scores for stroke patients with and without cold hemiplegic arms, including symptoms such as coldness, pain, heat, numbness, pins/needles, weakness, and dependence. The study findings indicate an asymmetry in the blood flow to normal hands in this elderly group, with patients having symptoms in the unaffected hand used as a control. The data is analyzed using the THERMOSOFT computer software package, and the median finger temperatures at each time point are calculated for both hands. The study also includes water-filled plethysmographs to measure blood flow in each hand, with healthy subjects showing a large normal variability.

during the rewarming period of 10 minutes. The results were analyzed by a coworker who was unaware of the characteristics of the patients using the THERMOSOFT (EIC, Inc) computer software package. Values for the temperature of the tips and bases of the index, middle, and ring fingers were obtained for each time point in both hands. Temperature results were obtained in the thermoneutral state and at 0, 3, 5, and 10 minutes after cooling. The median finger temperatures at each time were calculated for both hands.

We used water-filled plethysmographs to measure blood flow in each hand. In healthy subjects there is a large normal variability.
obtained and the known hand volume, we calculated blood flow per 100 mL of tissue per minute. The Wilcoxon matched-pairs signed rank test was used to test for significance between hemiplegic and unaffected hands. The Mann-Whitney rank sum test was used to test for significance between hemiplegic arm, and 10 denied coldness in the limb.

An already known volume. From the slope of the tracings measuring the volume of water displaced from a container with time causes water to be displaced, which is measured with a transducer and printed onto a chart recorder. At each temperature eight to 10 readings of blood flow were obtained with the fingers of the hemiplegic hand being colder. Therefore, we used two plethysmographs arranged in parallel to measure flow in the two hands simultaneously.

The patients were seated comfortably and the hands placed in the water chambers, which were above heart level. Wrist cuffs were then applied on both sides, and the water in both chambers was circulated by a pump at a thermostatically controlled temperature, initially 32°C. To obtain a reading of flow to the hemiplegic hand was significantly lower than the unaffected hand at all temperatures. At 32°C the median blood flow difference was 1.3 mL·100 mL⁻¹·min⁻¹; at 30°C and 28°C the median differences were 1.1 and 0.8 mL·100 mL⁻¹·min⁻¹, respectively. In those patients not complaining of a cold arm, there was no difference in blood flow between the hands at any temperature. In the small group of healthy age-matched subjects (n=6) there was also no difference in blood flow between the two hands at any temperature (Table 4).

Results

Of the 21 patients studied, 11 complained of a cold hemiplegic arm, and 10 denied coldness in the limb. Patients were matched for age but not for sex or side of hemiplegia. In addition, the symptomatic group had a lower mean motoricity score (Table 1).

Mean symptom scores were calculated for both patient groups (Table 2). Coldness of the arm was a prominent symptom in our study group (mean symptom score of 2.2 versus 3.4 for weakness).

Twenty of the 21 patients underwent thermography, 10 with cold arms and 10 subjects without this symptom (Table 3). In the symptomatic group blood flow to the hemiplegic hand was significantly lower than the unaffected hand at all temperatures. At 32°C the median blood flow difference was 1.3 mL·100 mL⁻¹·min⁻¹; at 30°C and 28°C the median differences were 1.1 and 0.8 mL·100 mL⁻¹·min⁻¹, respectively. In those patients not complaining of a cold arm, there was no difference in blood flow between the hands at any temperature. In the small group of healthy age-matched subjects (n=6) there was also no difference in blood flow between the two hands at any temperature (Table 4).

Discussion

This study was prompted by the observation that some patients have an unpleasant feeling of coldness in the hemiplegic arm after a stroke. The symptom developed within days in some patients but more commonly took weeks or months to become prominent. The severity of the problem varied considerably, but most of our patients were constantly aware of the symptom and obtained only limited relief from local measures such as gloves or hot water bottles. While our subjective rating system is crude, the comparison with other problems after stroke showed that coldness in the arm was surprisingly prominent in our study group (mean symptom score of 2.2 versus 3.4 for weakness). It is of interest that the group with coldness complained of more symptoms overall.

We investigated skin temperature and blood flow, but another possible mechanism producing the symptom might be abnormal temperature perception due to the stroke. Damage to the parietal lobe might cause altered interpretations of limb temperatures. In general, patients with left-sided paralysis are more likely to have perceptual problems than those with right-sided weak-

Fig 4. Bar graph shows median temperature difference between hands during cold stress test. Difference represents temperature of unaffected hand minus temperature of hemiplegic hand. If the hemiplegic hand is colder, the difference will be positive. There is a significant difference between the symptomatic and asymptomatic patients at all time points (Mann-Whitney U test). IQR indicates interquartile range.
ness. In our small series, 6 of 11 symptomatic patients had right-sided weakness, suggesting that altered perception is unlikely to be the major factor in the genesis of this phenomenon. However, sensory impairment or inattention may play a role in deciding who develops symptoms. One patient in the asymptomatic group had a markedly colder hemiplegic hand and reduced hand blood flow. This patient had sensory deficits on examination and a right parietal infarct on cranial computed tomographic scan. Patients with other neurological lesions such as poliomyelitis develop cold limbs, and some work on peripheral circulatory changes has been reported. Little evidence has been found for sympathetically mediated vasomotor responses, although initial success was claimed for sympathectomy in cold postpolio limbs. Instead, it is suggested that venous congestion of the limb results in uncontrolled heat loss. Venous congestion is suggested because of the violet hue of extremities in these patients and vascular microscopy showing dilated venules. Our patients did not show any red or purple color change in the affected limb, and there was no evidence of edema on clinical examination.

Infrared thermography provides an accurate measure of skin temperature. Furthermore, it is noninvasive and well tolerated by patients and has been used extensively in the evaluation of vasospastic conditions. There may be a temperature difference of up to 0.25°C between the hands in healthy people. The thermographic results showed that members of our group with symptomatic coldness do indeed have lower resting finger temperatures in the hemiplegic hand, and the variation between the two sides is well in excess of that seen in healthy subjects. Those hemiplegic stroke patients who did not complain of a cold arm had a much smaller difference in temperature between the hands at rest. This difference in temperature was within the normal range described in healthy people. However, the finger temperatures were lower in both hands in the asymptomatic group. It is not clear why these patients did not complain of coldness. We did not test thermal sensory thresholds in our patients, but this has been studied formally in stroke patients. The sensory threshold to external skin cooling in the hemiplegic arm was elevated in 6 of 17 patients. It was also found that sensory thresholds for temperature were elevated in 3 of 10 patients with no clinically detectable deficit in temperature sensation, and ipsilateral alterations in temperature perception were also noted. As already mentioned, one asymptomatic patient was known to have a sensory deficit, which may explain the lack of cold sensation, since the arm was colder by several degrees.

Previous temperature studies in the hemiplegic limb have been conflicting. Most of these studies showed an increased temperature of the hemiplegic arm, with initial warmth of the limb in the acute phase and coldness in the chronic phase. More recent work found that the skin temperature in the axilla of the hemiplegic arm was lower than that in the unaffected arm. All of these reports have investigated unselected hemiplegic patients with no perception of abnormal temperature in the arm. By selecting a group of patients with symptomatic coldness of the hemiplegic arm, we have shown a lower skin temperature and markedly lower blood flow in the hemiplegic hand compared with the unaffected hand. In some of the asymptomatic patients the affected arm was indeed warmer than the contralateral arm, in some cases by more than 1°C, suggesting that hemiplegic patients have a range of temperature changes in the affected arm.

The blood flow to the hemiplegic hand was significantly reduced compared with the unaffected arm in the symptomatic group but not in the asymptomatic group. We measured whole hand blood flow, which has a higher proportion of flow for nutrition compared with finger flow, which is largely related to thermoregulatory function. This explains why there is no direct correlation between our blood flow measurements and finger tip skin temperature. The mechanism causing the reduction in blood flow to the hemiplegic hand is unknown. One might postulate that simple disuse could account for the change, and this may be true for the forearm with its large muscle groups. However, the hand comprises proportionately more skin and less muscle, so that sympathetically mediated vasomotor tone is prob-

ably more important in determining blood flow than local mediators produced by active muscle. Reflex sympathetic dystrophy is another complication of stroke that produces symptoms in the hand, but our patients did not exhibit other recognized features of the condition. Only one symptomatic patient described any pain in the arm. Pain is not always present in the extremity in reflex sympathetic dystrophy, although it is reported to occur in the majority of cases. In addition, none of our patients exhibited evidence of swelling of the hand. Skin temperature, particularly in the fingers, largely reflects the state of tone in the skin vasculature. Large numbers of arteriovenous anastomoses are present in the fingers. Constriction in the precapillary sphincters due to various influences causes blood to be diverted away from the skin via these anastomoses. Constricting influences include $\alpha_2$ receptor–mediated sympathetic stimulation, circulating norepinephrine, and possibly 5-hydroxytryptamine, although the former mechanism is by far the most important.

Is it possible that vascular reactivity is altered in the hemiplegic arm after stroke? After deep inspiration or cough, vasoconstriction occurs in the limbs, which is spinal mediated. This vasoconstriction is greater in tetraplegic subjects, indicating a descending inhibitory influence on the area of the cord responsible for the response. Abnormal persistent vasoconstriction due to a spinal reflex would explain the reduced blood flow to the hemiplegic hand shown in this study. Another possibility is that these patients have an enhanced sensitivity to endogenous vasoconstrictors only on the hemiplegic side. An animal model of arterial denervation demonstrated hypersensitivity of vascular smooth muscle to constrictor influences. Lesions in the innervation of the fingers commonly result in cold intolerance due to a disturbance in vasoregulation. There is also evidence that diabetic patients with peripheral neuropathy have such enhanced sensitivity to vasoconstrictors. Although this is a lower motor neuron lesion, sympathetic fibers are affected, and it may be that the autonomic control of vasomotor tone is altered in hemiplegic patients via a lesion in the sympathetic system.

Coldness in the hemiplegic hand is a troublesome and unpleasant symptom in some patients after stroke. We have objectively shown marked vasomotor abnormalities in this small group of symptomatic patients. Clinicians caring for stroke patients should be aware of the symptom. Explaining that the symptom is not uncommon may give some reassurance, and local warming can sometimes afford relief. The next step is to determine what might be done to improve this symptom, and future studies might investigate the efficacy of vasodilators.
