Background—Impaired platelet function has been reported in acute myocardial infarction (AMI) and stroke. However, prospective data on the changes of platelet status in patients before the occurrence of hemorrhagic stroke after thrombolytic therapy are unavailable.

Case Description—An 86-year-old male patient was among the 23 AMI patients enrolled in the platelet study for the GUSTO-III trial. He received 325 mg of aspirin daily for at least 6 years, suffered an AMI, and was successfully reperfused with alteplase, but after 44 hours developed a large hemorrhagic stroke resulting in paraplegia. Platelet aggregation and receptor expression were measured by flow cytometry and ELISA before thrombolysis and at 3, 6, 12, and 24 hours thereafter. The percentage of platelet aggregation was lower in the stroke patient at every time point when induced by 5 µmol/L of ADP, by 10 µmol/L of ADP, and by thrombin than in the rest of the AMI group. Ristocetin and collagen-induced aggregability were within the group range. Decreased platelet glycoprotein Ib, IIb, IIIa, and IIb/IIIa and vitronectin receptor expression were observed in the stroke patient. No other differences in p24 (CD9), very late antigen-2, P-selectin, and platelet/endothelial cell adhesion molecule-1 expression were determined.

Conclusions—Profound depression of platelet status preceded the occurrence of hemorrhagic stroke in an elderly long-term aspirin user treated with thrombolytic therapy. Initial “exhausted” platelets may be responsible for the increased risk for hemorrhagic stroke after coronary thrombolysis. (Stroke. 1998;29:235–238.)

Key Words: hemorrhagic stroke ■ myocardial infarction ■ platelets ■ thrombolysis

Platelets have been implicated as important components in the natural history of acute myocardial infarction (AMI) and stroke. Thrombolytic agents remain the cornerstone of treatment for patients with AMI, whereas intracerebral bleeding is the most serious complication of their use. There is substantial evidence from in vitro and animal studies that impaired platelet function occurs after thrombolytic therapy and may play a role in the occurrence of intracranial hemorrhage. However, prospective dynamic data on the platelet status in patients before the occurrence of hemorrhagic stroke after thrombolytic therapy for AMI are unavailable.

We describe an elderly patient with an AMI who was enrolled in the GUSTO-III trial and underwent serial measurements of platelet aggregability, soluble receptor levels, and major surface receptor expression who later developed an intracerebral hemorrhage.

Case Report
An 86-year-old man with no prior cardiac history was admitted to the emergency department of St Agnes Hospital with 2.5 hours of left arm pain and chest discomfort. Blood pressure was 129/75 mm Hg, and pulse was 85 beats per minute. The physical examination was unremarkable. Past medical history was relevant for a hemicolectomy for villous adenoma. There was no history of bleeding diathesis or tobacco or alcohol use. The patient had received 325 mg of aspirin daily for the last 6 years. There were no other concomitant medications. The electrocardiogram demonstrated normal sinus rhythm with Q waves in leads V1 through V3 and ST segment elevation in leads V1 through V4, indicating an acute anteroseptal myocardial infarction. The white blood cell count was 8400/mL, platelet count was 196 000/mL, and the hematocrit was 44.5%. The blood urea nitrogen was 14 mg/dL, and creatinine was 1.1 mg/dL. The activated partial thromboplastin time was 34 seconds. The prothrombin time was 14 seconds.

The patient was treated with 325 mg of aspirin and 5000 U of intravenous heparin, followed by a continuous infusion of heparin as recommended in the GUSTO-III protocol. The patient was randomized to treatment with 100 mg of alteplase (15 mg bolus followed by 85 mg infusion over 90 minutes).
Platelets, Stroke, and Thrombolysis

Chest pain resolved within the first hour, and there was no evidence of congestive heart failure or arrhythmia. The peak creatine kinase (CK) was 554 IU/L, and peak CK-MB was 51 IU/L. Heparin was discontinued after 24 hours. At 36 hours, the activated partial thromboplastin time was 40 seconds, and the platelet count was 211 000/mL.

Approximately 44 hours after admission, the patient developed progressive confusion and left hemiplegia. A computed tomographic scan of the head demonstrated at least three areas of focal intracerebral hemorrhage. In light of these findings, aspirin was discontinued. An echocardiogram demonstrated anteroseptal hypokinesis and ejection fraction estimated at 40% to 45%, with no significant valvular heart disease. No embolic foci were identified. The neurological status improved after a prolonged hospitalization, and the patient was transferred to a subacute facility for further rehabilitation.

Blood samples were obtained before thrombolysis and at 3, 6, 12, and 24 hours thereafter. The table summarizes the baseline platelet aggregability in response to different agonists, flow cytometry of platelet surface receptors, and ELISA measurements of soluble antigens in the described patient compared with the rest of the AMI group and healthy control subjects.

AMI indicates acute myocardial infarction; GP, glycoprotein; VLA, very late antigen; and PECAM, platelet-endothelial cell adhesion molecule.

Results are expressed as mean±SD. Ranges are given in parentheses.
The present report emphasizes the potential importance of baseline platelet characteristics in the pathogenesis of hemorrhagic stroke after thrombolytic therapy for AMI. We attempted to correlate antecedent platelet status by using conventional aggregometry, ELISA, and flow cytometry techniques, with an episode of hemorrhagic stroke in the oldest patient enrolled in the GUSTO-III platelet study.

The major complication of thrombolytic therapy is hemorrhagic stroke, which occurs in 1.2% to 1.9% of treated AMI patients. Platelets have been implicated in both ischemic and hemorrhagic stroke. However, all of these studies have been performed in the relatively late phases of acute stroke and could be confounded by the natural history of the disease and the effects of various concomitant medications. The prospective assessment of the platelet status in the controlled clinical trial provides us with a unique opportunity to characterize the patient’s platelets before the occurrence of stroke.

Dynamic changes of the glycoprotein IIb/IIIa expression (A), very late antigen (VLA)-2 (B), and platelet–endothelial cell adhesion molecule (PECAM)-1 (C) during the first 24 hours after thrombolysis. ○ represents patient with future stroke; □ represents the rest of the AMI population.

**Discussion**

The present report emphasizes the potential importance of baseline platelet characteristics in the pathogenesis of hemorrhagic stroke after thrombolytic therapy for AMI. We attempted to correlate antecedent platelet status by using conventional aggregometry, ELISA, and flow cytometry techniques, with an episode of hemorrhagic stroke in the oldest patient enrolled in the GUSTO-III platelet study.

The major complication of thrombolytic therapy is hemorrhagic stroke, which occurs in 1.2% to 1.9% of treated AMI patients. Platelets have been implicated in both ischemic and hemorrhagic stroke. However, all of these studies have been performed in the relatively late phases of acute stroke and could be confounded by the natural history of the disease and the effects of various concomitant medications. The prospective assessment of the platelet status in the controlled clinical trial provides us with a unique opportunity to characterize the patient’s platelets before the occurrence of stroke.

It should be noted that none of the measured platelet aggregation agonists, soluble antigens, or surface receptors served as a specific marker exclusively affected in the described patient. In contrast, we found a profound depression of multiple platelet-related characteristics. This finding leads us to an important observation. We can no longer hypothetically assume that platelets are necessarily systemically activated during the initial pre-reperfusion phase of AMI.

Another meaningful issue is the long-term use of relatively high doses of aspirin, which was documented in the described patient. However, there is no evidence that depressed platelet characteristics in this patient were directly related to the antecedent aspirin therapy.

This preliminary report also suggests that the adequate and timely assessment of platelet activity may be critical in assessing the risk for hemorrhagic stroke. Bleeding events after standard thrombolytic and/or antiplatelet therapy could be related to the decreased platelet characteristics in such patients. It is not clear whether we should uniformly use aggressive thrombolytic strategies without individual assessment of platelet status in AMI patients. Based on the present case, it is reasonable to speculate that the early bleeding complication observed after modern therapy could be, at least in part, related to depressed baseline platelet characteristics.

In conclusion, the ability to define patients at risk of hemorrhagic stroke after thrombolysis in AMI cannot be overstated. If platelets indeed are vital elements of the acute coronary and cerebrovascular events, then their characteristics could affect the response to thrombolytic therapy and clinical outcome. In our case, profound depression of platelet status preceded the occurrence of hemorrhagic stroke in an elderly patient who was successfully reperfused. Dysfunctional platelets may be responsible for the increased risk of provoking hemorrhagic stroke after thrombolysis. Further analysis of the baseline platelet status and its clinical significance during acute vascular syndromes remains to be determined.

**Acknowledgments**

This work was supported, in part, by Medtronic, Inc, and by Boehringer Mannheim GmbH. We are indebted to the staff of the emergency departments and critical care units of the St Agnes and the Union Memorial Hospitals. We would like to thank Kenneth A. Ault, MD, for his advice with the flow cytometry techniques and Barry S. Coller, MD, for his constructive comments and helpful suggestions on the manuscript.
