Hyperglycemia Enhances Extracellular Glutamate Accumulation in Rats Subjected to Forebrain Ischemia

Ping-An Li, MD, PhD; Ashfaq Shuaib, MD, FRCP; Hiro Miyashita, MS; Qing-Ping He, MS; Bo K. Siesjö, MD, PhD

Background and Purpose—An increase in serum glucose at the time of acute ischemia has been shown to adversely affect prognosis. The mechanisms for the hyperglycemia-exacerbated damage are not fully understood. The objective of this study was to determine whether hyperglycemia leads to enhanced accumulation of extracellular concentrations of excitatory amino acids and whether such increases correlate with the histopathological outcome.

Methods—Rats fasted overnight were infused with either glucose or saline 45 minutes before the induction of 15 minutes of forebrain ischemia. Extracellular glutamate, glutamine, glycine, taurine, alanine, and serine concentrations were measured before, during, and after ischemia in both the hippocampus and the neocortex in both control and hyperglycemic animals. The histopathological outcome was evaluated by light microscopy.

Results—There was a significant increase in extracellular glutamate levels in the hippocampus and cerebral cortex in normoglycemic ischemic animals. The increase in glutamate levels in the cerebral cortex, but not in the hippocampus, was significantly higher in hyperglycemic animals than in controls. Correspondingly, exaggerated neuronal damage was observed in neocortical regions in hyperglycemic animals.

Conclusions—The present results demonstrate that, at least in the neocortex, preischemic hyperglycemia enhances the accumulation of extracellular glutamate during ischemia, providing a tentative explanation for why neuronal damage is exaggerated. (Stroke. 2000;31:183-192.)

Key Words: cerebral ischemia ■ excitatory amino acids ■ glutamates ■ hyperglycemia ■ pathology ■ rats

It has been known for 2 decades that preischemic hyperglycemia aggravates brain damage due to transient global or forebrain ischemia in experimental animals. Clinical studies on diabetic and hyperglycemic patients support the notion that raised plasma glucose concentrations augment brain lesions associated with stroke. The aggravation in global ischemia has the following features: (1) the neuronal necrosis evolves more rapidly, (2) additional structures are recruited, (3) selective neuronal necrosis is transformed into panencephalitis, and (4) postischemic seizures develop and then end in fatal status epilepticus (for reviews, see References 2 and 3).

The mechanisms involved have not been adequately defined. Hyperglycemia probably acts by enhancing accumulation of lactate plus H⁺, thereby exaggerating the reduction of intracellular and extracellular pH (pHi and pHₑ, respectively). In support of this notion are the results reported by Smith et al. (1986) showing that hyperglycemic subjects have more profound decreases in pHi and pHₑ during ischemia, and those of Katsura et al. (1992), demonstrating an almost linear correlation between the increase in lactate during ischemia and the fall in pHi and pHₑ. Furthermore, Li et al. (1994, 1995) reported a very narrow threshold of plasma glucose concentration (10 to 14 mmol/L) and of pHₑ (6.3 to 6.5), above and below which brain damage was exaggerated and postischemic seizures were triggered, supporting the notion of a critical pH range.

It has been established that excitatory amino acids (EAAs), notably glutamate, play a pivotal role in neuronal death. Recent studies demonstrate that mitochondria are a primary target of glutamate toxicity. Glutamate-mediated massive influx of calcium triggers opening of a mitochondrial permeability transition pore, which may contribute to cell death. The possibility that hyperglycemia exaggerates brain damage by increasing the efflux of glutamate has not been established. In the present study we used in vivo microdialysis coupled with high-performance liquid chromatography (HPLC) techniques to detect the pattern of changes in extracellular glutamate, glutamine, glycine, taurine, alanine, and serine concentrations in brain tissue of rats subjected to 15 minutes of forebrain ischemia. We also evaluated the

183
pathological outcome in separate groups of animals. The hypothesis tested was whether hyperglycemia enhances the rise in extracellular glutamate concentration and whether it correlates with exaggerated tissue damage.

Materials and Methods
Male Wistar rats of a specific-pathogen-free strain (Charles River Animals Facility, Quebec, Canada), weighing 300 to 390 g, were used in the present experiments. All animal use procedures were in strict accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals and were approved by the Animal Ethics Committee of the University of Saskatchewan. All efforts were made to minimize animal suffering, to reduce the number of animals used, and to use alternatives to in vivo techniques, if available.

Implantation of Guide Cannulas
Five to 7 days before microdialysis experiments, the animals were anesthetized with Equiten (a mixture of pentobarbital, propylene glycol, ethanol, MgSO4, and chloral hydrate). The hair on the skull was shaved, and the skin was treated with an antiseptic. The animals were placed in a stereotaxic frame (David Kopf) for positioning of the guide cannula of the microdialysis probes in the hippocampus and cortex. The skull was exposed and treated with 3% hydrogen peroxide. Three metal screws were firmly connected to the skull for fixation of a guide cannula on the skull. Two burr holes were made in the cranium. One was made overlying the left dorsal hippocampus 3.8 mm posterior to bregma, 2.5 mm lateral to midline, and 1.5 mm ventral to dura. The other was drilled over the right parietal cortex 3.0 mm posterior to bregma, 5.0 mm lateral to midline, and 2.0 mm ventral to dura. The probe length was 2 mm longer than the guide cannula, resulting in a final depth, after inserting the probe, of 3.5 and 4.0 mm in the hippocampus and neocortex, respectively. After insertion, the guide cannulas were fixed to the skull by placing dental acrylic around the cannula. The scalp was then closed surgically, and the animal was returned to its home cage, being individually housed.

Operative Procedures
The animals were fasted overnight before surgery with free access to water. Anesthesia was induced by inhalation of 3.5% halothane in a mixture of N2O and O2 (60:40) and was maintained with 1.0% to 1.5% halothane in N2O and O2 (60:40) during the operation. A rectal thermometer (Thermocouple Thermometer, Bar- nant Company) was inserted, and another thermometer was placed subcutaneously on the skull to monitor the body and head temperatures, which were maintained as close to 37°C as possible by lamp heating during the whole process. Electroencephalographic (EEG) needles were inserted into the temporal muscles on the skull. The heating during the whole process. Electroencephalographic (EEG) 

Detection and Quantification of EAAs
Analysis of extracellular concentrations of glutamate, glutamine, glycine, taurine, alanine, and serine in the microdialysate was performed by HPLC (model 510 Liquid Pump equipped with a 10-μm filter; Millipore Corporation, Waters Chromatography Division) with electrochemical detection after precolumn derivatization by methods described previously in detail. A 5.0-μm Delta-Pak Cartridge filter was installed between the pump and a 715 Ultra Wisp Sample Processor (Millipore Corporation). A 100-μm microdialysis probe, preceded a reverse-phase Nova-Pak steel column (Waters) (3.9 X 150 mm) (4.0 particle size), which in turn, was connected to a model 460 High Sensitivity Waters Electrochemical Detector. Precolumn derivatization of amino acids with o-phthalaldehyde/β-mercaptoethanol was done before electrochemical detection. Using the 715 Ultra Wisp Sample Processor (Millipore Corporation), we employed a fully automated system for the derivatization procedure to minimize the degradation of amino acids. This sample processor dispenses and mixes the reagent thoroughly into the microdialysis perfusate in a 200-μL loop. The injection was made precisely 2 minutes after the reaction time. Amino acid concentrations were measured and stored in the computer for future analysis with the Baseline 810 Chromatography Work Station Processing System (Waters). The mobile phase consisted of 0.01 mol/L disodium hydrogen orthophosphate, 0.13 mmol ethylenediaminetetraacetic acid–sodium salt, and 20% methanol. External standards of 0.625, 1.25, 2.5, 25, 100, 300, and 1200 pg/10 μL were used for postex- periment probe calibration for all the amino acids.

Quantification of Brain Damage
None of the normoglycemic animals subjected to 15 minutes of forebrain ischemia at 37°C body and brain temperature developed posts ischemic seizures, and all survived for 7 days, allowing conven-
tional histopathological evaluation of brain damage. In hyperglyce-
memic animals, however, survival was severely restricted. Thus, when
6 animals in a pilot study were allowed to wake up after the
ischemia, all developed seizures during the first 1 to 3 hours and
subsequently died in status epilepticus. For that reason, brain damage
in hyperglycemic animals was evaluated after only 3 hours of
reperfusion and was compared with that incurred in normoglycemic
animals.

For perfusion-fixation, animals were reanesthetized with 3% halothane, tracheotomized, and artificially ventilated. The thorax
was opened, and a perfusion needle was transcardially inserted into
the ascending aorta. The brains were first rinsed with saline for 30
seconds and then perfusion-fixed with 4% formaldehyde buffered to
pH 7.35. The brains were cut coronally in 2- to 3-mm-thick slices,
dehydrated, embedded in paraffin, sectioned in 5 μm with a Reichert
sledge microtome, and then stained with acid fuchsin and celestine
blue, as described by Auer et al (1984).14 The sections were
examined in a blinded fashion at a magnification of ×400. Any
necrotic neurons of both hemispheres were counted in one coronal
section at the level of bregma −3.8 mm in the hippocampal CA1
sector, and the percentage of necrotic neurons was calculated by
dividing the number of necrotic neurons by the total number of
existing neurons at the identical brain section level in nonoperated
normal animals. Damage in the neocortex was too extensive to count
through the whole section in hyperglycemic animals. Therefore, the
damage was assessed by counting dead neurons in a strip, 400 μm
wide, through layers 1 to 6 at a site just between the midline and the
entorhinal fissure at the level of bregma −3.8 mm. The average total
number of neurons in this area was 450 per stripe in nonoperated
normal animals. The percentage of necrotic neurons was calculated.

Statistical Analysis
EAA concentrations are presented as mean±SEM. Paired t test (for
chronological data versus preischemic baseline) and unpaired t test
(for hyperglycemia versus normoglycemia at identical sampling
time) were applied for statistical analysis. All tests were 2-sided.

P<0.05 was considered statistically significant.

Results

Physiological Parameters and Seizure Incidence
Blood glucose concentrations were 90.0±14.4 and
372.6±27.2 g/100 mL in normoglycemic and hyperglycemic
animals, respectively. Both head and body temperatures were
maintained to 37.2±0.2°C. Mean arterial blood pressure was
maintained at 120±13 mm Hg. Ventilation was adjusted to
give an arterial pH of 7.4±0.2, Pco2 of 40.2±2.2 mm Hg, and
Po2 of 104±18 mm Hg. There were no statistically significant
differences between normoglycemic and hyperglycemic
groups. EEG was continuously monitored during the entire
microdialysis periods, and no subclinical seizure activities
were observed in either normoglycemic or hyperglycemic
rats. In the series for histopathological study, no animal
developed postischemic clinical seizures in normoglycemic
subjects, while 4 of 6 showed seizure in hyperglycemic
animals. Pathological evaluation showed that the 2 seizure-free
rats had the same extent of damage as rats with seizures.

Histopathological Outcome
Predictably, normoglycemic animals did not have any dam-
age in the hippocampal CA1 sector after 3 hours of recovery,
and only a few scattered necrotic neurons were found in the
neocortex. When the recirculation was prolonged for 7 days,
the ischemia gave rise to nearly 100% damage in the CA1
sector and 30% damage in the neocortex. In the hyperglyce-
mic animals, only a few necrotic neurons could be observed
in the CA1 sector (5% damage) after the 3-hour recovery
period. The small amount of CA1 damage in both normogly-
cemic and hyperglycemic animals after 3 hours of reperfusion
was probably due to the fact that such a short period of
reperfusion did not allow the CA1 damage to mature.15
Damage in the neocortex was dramatically exaggerated in
hyperglycemic rats (P<0.01 versus normoglycemic con-
trols). Panneurotic lesions were observed in 5 of 6 hyperglyc-
cemic animals; additionally, status spongiosus suggested
edema. Figure 1 contains representative microphotographs
showing neuronal damage after 3 hours of reperfusion in the
neocortical area in both normoglycemic and hyperglycemic
rats. Adverse effects of hyperglycemia on tissue damage
could also be observed in other brain areas. Thus, while only
mild to moderate damage was observed in the striatum and
thalamus in normoglycemic animals after 7 days of recovery,
panneurosis occurred in these structures of hyperglycemic
animals (data not shown) as early as after 3 hours of recovery.
In addition, damage to the cingulate cortex and the substantia
nigra was not observed unless hyperglycemia was instituted
(data not shown).

Extracellular Amino Acids
Three microdialysis samples were collected at 15-minute
intervals to obtain a stable preischemic EAA baseline. Since
there were no differences among them, the results of these 3 samples were pooled and served as baseline values.

**Glutamate Concentrations**

Preischemic extracellular glutamate baseline concentrations in both the dorsal hippocampal region and the neocortex were \(20 \pm 2.2\) pg/10\(^\mu\)L, with no differences among sham, normoglycemic, or hyperglycemic subjects. The changes in extracellular glutamate concentrations in the hippocampal CA1 subregion before, during, and after ischemia are summarized in Figure 2, top panel. In sham-operated animals, the extracellular glutamate concentrations were constant throughout the 180-minute sampling period. In normoglycemic ischemic animals, extracellular glutamate concentration increased from \(20.3 \pm 2.2\) to \(284.8 \pm 24.6\) pg/10\(^\mu\)L (mean \(\pm\)SEM; 14.0-fold) after the induction of ischemia \(P, 0.0001\). The glutamate concentrations remained elevated after 15 minutes of recirculation \(150.8 \pm 34.7\) pg/10\(^\mu\)L; \(P, 0.01\)) and returned to near-control levels thereafter. Changes in glutamate of hyperglycemic rats were similar to those recorded in normoglycemic ones. Thus, glutamate content increased from \(19.4 \pm 2.2\) to \(295.5 \pm 72.3\) pg/10\(^\mu\)L during ischemia and remained elevated after 15 minutes of recirculation \(178.4 \pm 42.6\) pg/10\(^\mu\)L; \(P, 0.01\), subsequently returning to baseline.

The glutamate transients were different in the neocortex compared with the hippocampus. First, the elevation of glutamate concentration during ischemia in normoglycemic animals was less than that in the hippocampus \(91.9 \pm 26.1\) versus \(284.8 \pm 24.6\) pg/10\(^\mu\)L; \(P, 0.01\). Second, and most importantly, hyperglycemic animals showed a more pronounced increase in glutamate content than normoglycemic ones. As shown in Figure 2, bottom panel, glutamate levels increased from \(24.3 \pm 1.7\) to \(91.9 \pm 26.1\) pg/10\(^\mu\)L (3.8-fold; \(P, 0.01\)) in normoglycemic ischemic animals, whereas the increase in glutamate was from \(19.6 \pm 2.4\) to \(200.5 \pm 39.8\) pg/10\(^\mu\)L (10.2-fold; \(P, 0.001\)) in hyperglycemic animals. The peak value in hyperglycemic subjects was twice that in normoglycemic animals \(P, 0.05\).

**Glutamine**

Figure 3, top panel, illustrates changes in hippocampal glutamine concentrations. Extracellular glutamine concentrations in dialysate \(\text{mean} \pm \text{SEM}\) over the course of the experiment for 3 groups in the hippocampal CA1 region and in the neocortex. Glutamine was decreased in normoglycemic animals, and the decrease was more persistent in hyperglycemic animals. \(^*P, 0.05\) vs baseline. Abbreviations are as defined in Figure 2.

The baseline resting levels of glutamine were numerically higher in the hyperglycemic group than in the normoglycemic group. However, this difference was not statistically significant because of variations between animals. Compared with normoglycemic animals, hyperglycemic animals had a more prolonged and more long-lasting decrease in extracellular glutamine during the ischemic and reperfusion periods. Thus, extracellular glutamine contents remained lower than baseline during the 105 minutes of recirculation.
In the cortex, glutamine changes were not as pronounced as in the hippocampus (Figure 3, bottom panel). Significant decreases of glutamine concentration could only be detected at 15 minutes of recirculation in normoglycemic animals ($P_{0.05}$) and during the first 45 minutes of reperfusion in hyperglycemic animals. However, the results reinforce the impression that hyperglycemia prolongs the reduction in glutamine concentration.

**Glycine**

The alterations in the extracellular glycine concentration in the hippocampus are shown in Figure 4, top panel. Ischemia induced an abrupt increase in extracellular glycine concentration in both normoglycemic and hyperglycemic groups. Similar to the changes in glutamate, the peak concentrations were reached after the induction of ischemia, and increased levels were maintained during the immediate reperfusion period. Unlike glutamate, however, the increase in glycine was sustained in the postischemic period, and such a sustained increase lasted longer in hyperglycemic animals. In normoglycemic animals the glycine concentration returned to baseline level after 45 minutes of recirculation ($P_{0.05}$); however, it was persistently increased (except in the 120-minute sample) in hyperglycemic animals ($P_{0.05}$).

In the neocortex (Figure 4, bottom panel), glycine concentrations were moderately raised immediately after reperfusion and declined to baseline values at 60 minutes of recovery in the normoglycemic group. The increase in glycine concentration appeared somewhat delayed in the hyperglycemic rats, but it was sustained for a longer period than in the normoglycemic animals.

**Taurine**

Figure 5 shows the alterations of extracellular taurine concentration in the hippocampal and cortical regions. Transient increases of taurine in microdialysates were observed in both normoglycemic and hyperglycemic subjects, and increased values persisted for the first 30-minute period of recirculation ($P_{0.01}$). The peak values appeared slightly lower in hyperglycemic than in normoglycemic animals.

**Alanine**

Extracellular alanine concentrations in the hippocampal CA1 subregion and cortex are presented in Figure 6. In the hippocampus, alanine concentrations increased after ischemia in the saline-infused rats. Unlike other amino acids, alanine did not increase in concentration during ischemia and the immediate reperfusion phase, but an increase occurred 45 to 90 minutes after reperfusion. There was no major change in glucose-infused animals. Alanine changes in the cortex were similar to those in the hippocampus.

**Serine**

Extracellular serine concentrations are given in Figure 7. In both the cortex and the hippocampus, sham-operated animals had a higher serine level than the 2 ischemic groups. Thus, the neocortical values in hyperglycemic animals and hippocampal values in both normoglycemic and hyperglycemic groups...
were significantly lower than the values in the sham-operated group. Extracellular serine concentrations were not changed after ischemia and reperfusion in saline-infused rats. In animals infused with glucose, a decrease in serine concentration could be observed in the hippocampus and the cortex during ischemia. The decrease was also evident in samples collected after 15 to 60 minutes of reperfusion.

**Discussion**

When the present results are discussed, it should be kept in mind that even in normoglycemic animals, 15 minutes of ischemia at a brain temperature of 37°C is a relatively severe insult that, apart from giving close to 100% CA1 neuronal necrosis, kills ~30% of the neurons in the neocortical strip examined. Damage to both of these structures is delayed, the rate of evolution being faster in the neocortex than in the CA1 sector.15 It is thus possible to find reperfusion times when neocortical but not CA1 damage is observed.

With this model, hyperglycemia results in such a severe insult that survival is no longer possible, mainly because intractable seizures develop.6,7 However, the ischemia does not compromise reflow since the bioenergetic state recovers upon reperfusion16 and capillary patency remains intact.17 It is thus possible to use the first hour of reperfusion to study events that prime the tissue for seizures and secondary bioenergetic failure. In one respect, it would have been advantageous to employ 10 minutes of ischemia and to use a lower plasma glucose concentration since this would allow hyperglycemic animals to survive.6,7 However, that model carries the potential disadvantage of large interanimal variations.

Another consideration is the difference in pH_e (and pH_i) between the normoglycemic and hyperglycemic animals. As measured under comparable ischemic conditions, the differences in pH_e and pH_i are ~0.5 pH units, eg, pH_e falls from 7.3 to 6.8 in normoglycemic animals and from 7.3 to 6.3 in hyperglycemic animals.4,5 It is not known whether such a difference could affect amino acid release during ischemia. An additional consideration is the effect of anesthesia on the measurements of EEA concentrations. Equithesin contains magnesium, which is a noncompetitive NMDA antagonist, and therefore it would possibly have influenced the EEA levels. However, since equithesin was used for implantation of cannulas 5 to 7 days before microdialysis samples were collected, it is unlikely to have influenced the measurements of EEA conducted 5 to 7 days after the use of this anesthetic agent.

The rats that were kept under anesthesia for use in microdialysis experiments showed no subclinical seizure activity. Given the fact that the anesthesia obviously prevented seizure activity from occurring, it might influence the measurements of EEAs. However, increases of extracellular EEAs, including glutamate, were observed during ischemia and in the immediate reperfusion period (15 minutes). It is not likely that subclinical seizure activity develops at such an early stage in reperfusion.18 In support, Nakashima and Todd19 reported that anesthetic agents such as isoflurane and

Abbreviations are as defined in Figure 2.
pentobarbital do not influence the glutamate transient in rats subjected to complete global ischemia.

**Effect of Hyperglycemia on Brain Damage**

Preischemic hyperglycemia worsens the ischemic injury (for reviews, see References 2 and 3) Previous results have demonstrated that while ischemia of 10 to 15 minutes’ duration results in maximal CA1 damage in normoglycemic subjects, hyperglycemia aggravates damage in the parietal cortex, striatum, and thalamus and recruits the cingulate cortex, the CA3 sector of the hippocampus, and the substantia nigra in the damage process. The present results confirm these findings and provide an interesting observation of extensive neocortical injury already present after 3 hours of reperfusion. Predictably, damage to CA3 neurons was delayed to a later reperfusion period (see above). The mechanisms by which hyperglycemia exaggerates ischemic brain damage have not been clarified. Acidosis may be one of the key factors in hyperglycemia-related damage. This contention is supported by the findings that acidosis induced by superimposed hypercapnia augments selective neuronal necrosis in normoglycemic ischemic animals and in rats with hypoglycemic coma.

**Excitotoxic Theory and the Link Between Glucose and Increased Glutamate**

Numerous studies have shown that glutamate, when present in excessive amounts extracellularly, is neurotoxic. Glutamate and related EAAs activate postsynaptic glutamate receptors. Activation of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) type of glutamate receptor allows influx of Na\(^{+}\), Cl\(^{-}\), and water (and a small amount of Ca\(^{2+}\)) by way of receptor-gated channels. This leads to swelling of the neurons. Activation of the N-methyl-D-aspartate (NMDA) type of glutamate receptor opens a channel permeable to calcium, leading to intracellular calcium overload. The resulting massive increase in intracellular calcium has a number of consequences. The crucial event may be the assembly of a mitochondrial permeability transition pore, which then triggers release of cytochrome c from mitochondria, and a burst of production of reactive oxygen species.

Our results demonstrate that the rise in neocortical extracellular glutamate concentration during ischemia and in the immediate reperfusion period is more pronounced in hyperglycemic animals. Choi and colleagues previously tried to assess the effect of hyperglycemia on extracellular glutamate concentrations in rats subjected to brief periods of ischemia. Their samples were taken from the hippocampus. This may be why they did not observe an increased extracellular glutamate concentration in hyperglycemic rats.

More than a decade ago, Gaitonde et al (1987) described the pathway of glucose metabolism into EAAs. Approximately 70% of the \(^{14}\)C-labeled glutamate was formed from acetyl coenzyme and 30% by \(^{14}\)CO\(_2\) fixation of pyruvate after injection of [3,4,\(^{14}\)Cl]glucose. Thus, glutamate in the brain is formed by metabolism of glucose via the hexose monophosphate shunt as well as via the Embden-Meyerhof pathway. It cannot be argued that hyperglycemia enhances glutamate synthesis. However, we cannot anticipate a relationship between the total amount of glutamate formed and the amount available for release during ischemia. Hyperglycemia may also influence other factors determining the uptake of amino acids. As will be discussed below, changes in glial metabolism may explain some of the changes in glutamate and glutamine concentrations.

Glia cells carry the main responsibility of rapid posts ischemic removal of EAAs accumulated in extracellular space. Increases in glutamate and decreases in glutamine could be best explained by assuming that while some glial uptake of glutamate may persist during ischemia, at least initially, the subsequent metabolism of glutamate to glutamine is impeded. The reduced metabolism of glutamate by glial cells may be responsible for part of the extracellular glutamate overflow during ischemia. However, an increased neuronal efflux of glutamate is also likely to contribute.

The additional increase of glutamate concentration in hyperglycemic subjects may either reflect the fact that glucose enhances the formation and release of glutamate from presynaptic endings, as described by Gaitonde et al (1987), or reflect the fact that acidosis inhibits glutamate uptake by glial cells (astrocytes). A reduction in pH from 7.4 to 5.8 in primary rat astrocyte cultures causes a significant inhibition of glutamate uptake, and this inhibition is more pronounced when acidosis is combined with hypoxia. A similar situation may have existed in our experiments, in which severe acidosis is combined with cellular hypoxia.

It has been reported by Dietrich and colleagues (1993) that hyperglycemia causes breakdown of the blood-brain barrier following 20 minutes of global ischemia, and it may therefore account for the increase in the extracellular glutamate. However, since extracellular glutamate already increased during ischemia, it is unlikely that the extra increase in extracellular glutamate resulted from the breakdown of the blood-brain barrier.

It is not clear that an increased accumulation of glutamate in extracellular fluid, above that observed in normoglycemic animals, can explain the exacerbated cell damage in hyperglycemic subjects. However, since hyperglycemia-enhanced glutamate release is correlated with aggravated damage observed in the neocortical areas, it is therefore possible that the additional increase of glutamate concentrations in the extracellular space may be responsible, at least partially, for the aggravated damage in hyperglycemic animals. It is not clear why hyperglycemia enhances glutamate release in the neocortex but not in the hippocampus. Possibly, maximal accumulation of glutamate in extracellular fluid already occurs in normoglycemic rats; therefore, hyperglycemia cannot increase it further. It has been established that the hippocampus has an abundance of glutamatergic inputs. This agrees with our findings that the absolute values of extracellular glutamate were much higher in the hippocampus than in the neocortex. The failure of hyperglycemia to increase extracellular glutamate levels in the hippocampus is not compatible with any general hypothesis of a coupling between glutamate...
concentration and hyperglycemia-exaggerated damage; in fact, the data could be used to prove that such a coupling does not exist. However, because of its vulnerability to ischemic insults, the hippocampus could be a special case. Thus, although the CA1 damage matures more rapidly in hyperglycemic animals, Glutamine is a major metabolic precursor of glutamate. The reduction of extracellular glutamine may reflect utilization of intracellular glutamine for synthesis of glutamate or inhibition of synthesis due to depletion of energy stores. However, the decrease in extracellular glutamine could also be linked to an increased activity of the phosphate-activated glutaminase, a key enzyme in the synthesis of neurotransmitter glutamate, since tissue inorganic phosphate content increases markedly during ischemia, and calcium promotes phosphate activation of glutaminase. Inhibition of the glial enzyme glutamate synthetase, which converts glutamate to glutamine, has been reported during reperfusion after cerebral ischemia. Suppression of activity of this enzyme could result in both a reduction in glutamine efflux and synaptic glutamate accumulation.

Changes in Glutamine

Our results demonstrate that a large increase in glutamate efflux is coupled with a corresponding decline in glutamine efflux. The decrease of glutamine is sustained for a longer period in hyperglycemic animals. Glutamine is a major metabolic precursor of glutamate. The reduction of extracellular glutamine may reflect utilization of intracellular glutamine for synthesis of glutamate or inhibition of synthesis due to depletion of energy stores. However, the decrease in extracellular glutamine could also be linked to an increased activity of the phosphate-activated glutaminase, a key enzyme in the synthesis of neurotransmitter glutamate, since tissue inorganic phosphate content increases markedly during ischemia, and calcium promotes phosphate activation of glutaminase. Inhibition of the glial enzyme glutamate synthetase, which converts glutamate to glutamine, has been reported during reperfusion after cerebral ischemia. Suppression of activity of this enzyme could result in both a reduction in glutamine efflux and synaptic glutamate accumulation.

Prolonged Release of Glycine by Hyperglycemia

Glycine is located in presynaptic terminals. There are 2 types of glycine receptors, Gly 1 (the classic strychnine-sensitive inhibitory site) and Gly 2 (the strychnine-insensitive site). Gly 1 acts as an inhibitory neurotransmitter because of its ability to cause postsynaptic hyperpolarization. Gly 2 is associated with excitatory transmission since it potentiates NMDA activity. It has been assumed by some investigators that glycine levels are probably already saturated under physiological conditions and that changes in glycine are unlikely to make any difference with respect to NMDA receptor activation; however, many in vivo and in vitro experiments provide convincing data that NMDA-associated glycine sites are not saturated at physiological levels of glycine (for review and literature, see Reference 40). Delayed treatment with glycine site antagonists attenuates infarct size in focal ischemia. In the present study glycine concentrations increased during ischemia, and the elevated levels were sustained into the postischemic period. Such changes in concentrations of glycine have been previously reported. The sustained increase may help to explain the ongoing toxicity despite the return of glutamate to baseline levels. In the present study, when compared with normoglycemic animals, hyperglycemic animals had a much more prolonged elevation in glycine levels in both hippocampal and neocortical areas after ischemia. It is tempting to postulate that the rise in glycine modulates the action of glutamate in vivo during and after ischemia and may be responsible, at least partially, for the detrimental effect of hyperglycemia on neurological outcome.

In summary, the present results demonstrate that preischemic hyperglycemia enhances the accumulation of extracellular glutamate in the neocortex and that the enhanced increase of glutamate is correlated with exaggerated cell damage. The increase was observed during ischemia and in the immediate (15-minute) posts ischemic period. Hyperglycemia also prolonged the postischemic decrease in glutamate concentration normally seen during the initial 15 to 30 minutes of recirculation and gave rise to a sustained increase in glycine concentrations after recirculation. Changes in taurine, alanine, and serine concentrations were inconclusive. Thus, although extracellular taurine and alanine concentrations rose during ischemia and after reperfusion, no clear effects of hyperglycemia were observed.

It is clearly established that preischemic hyperglycemia worsens ischemic outcome in laboratory animals. There also is sufficient correlative human data for most clinicians to accept the conclusion that glucose infusion should be withheld in patients at risk for ischemic brain damage. This perhaps has greatest relevance to surgical patients, in whom ischemic events can often be presaged, and it is also relevant to patients undergoing cardiopulmonary resuscitation (CPR). For these reasons, dextrose-containing solutions are usually withheld from surgical patients, and the Advance Cardiac Life Support algorithm has been modified to recommend administration of normal saline as the principal intravenous solution during CPR.1,2

From a scientific perspective, it remains a paradox that giving glucose can worsen damage in ischemic tissue that is by definition deprived of sufficient substrate to maintain normal metabolic function. One likely mechanism for this is the enhanced lactic acidosis resulting from anaerobic metabolism of glucose, which is disproportionately more available than oxygen. However, in vitro studies have found that acidosis actually provides an advantage to cultured neurons deprived of metabolic substrate.3 Accordingly, although lactic acidosis, in part, explains hyperglycemia-augmented ischemic brain damage, other mechanisms are also likely involved.

It is widely accepted that disregulated glutamate metabolism during ischemia, and the concordant increase in extracellular glutamate concentration, contribute to ischemic brain injury. It has been known that hyperglycemia augments extracellular glutamate increases during ischemia.4 What is novel in the current work by Li et al is the attempt to correlate these changes with histological outcome. Rats were subjected to severe forebrain ischemia while either normoglycemic or hyperglycemic. Data from the hippocampus during transient cerebral ischemia monitored by intracerebral microdialysis. J Neurochem. 1984;43:1369–1374.

For normoglycemic rats, the period of ischemia was 40 minutes (n=5) and for hyperglycemic rats, the period of ischemia was 20 minutes (n=5). The rationale for this difference is that hyperglycemic rats have a more pronounced effect of glucose on neurotransmitter release. The rationale for this is that hyperglycemic rats have a more pronounced effect of glucose on neurotransmitter release. The rationale for this is that hyperglycemic rats have a more pronounced effect of glucose on neurotransmitter release.

For these reasons, presurgical patients undergoing cardiopulmonary resuscitation (CPR) generally receive glucose-free solutions. However, in the current study, hyperglycemic rats demonstrated a greater increase in glutamate levels during ischemia, which suggests that glucose-glutamate upregulation occurs in vivo. This finding is consistent with previous studies demonstrating that hyperglycemia increases extracellular glutamate levels during ischemia.

Li et al: Effect of Glucose on Excitatory Amino Acids

It is widely accepted that glucose infusion should be withheld in patients at risk for ischemic brain damage. This has been known that hyperglycemia augments extracellular glutamate increases during ischemia. What is novel in the current work by Li et al is the attempt to correlate these changes with histological outcome. Rats were subjected to severe forebrain ischemia while either normoglycemic or hyperglycemic. Extracellular amino acid concentrations were measured in both cortex and hippocampus. Data from the hippocampus were more difficult to interpret. Again, ischemia increased glutamate concentrations. However, in vitro studies have found that acidosis actually provides an advantage to cultured neurons deprived of metabolic substrate.3 Accordingly, although lactic acidosis, in part, explains hyperglycemia-augmented ischemic brain damage, other mechanisms are also likely involved.

From a scientific perspective, it remains a paradox that giving glucose can worsen damage in ischemic tissue that is by definition deprived of sufficient substrate to maintain normal metabolic function. One likely mechanism for this is the enhanced lactic acidosis resulting from anaerobic metabolism of glucose, which is disproportionately more available than oxygen. However, in vitro studies have found that acidosis actually provides an advantage to cultured neurons deprived of metabolic substrate.3 Accordingly, although lactic acidosis, in part, explains hyperglycemia-augmented ischemic brain damage, other mechanisms are also likely involved.

ever, because hyperglycemic animals typically died within the first few hours after ischemia, histological information could not be obtained when full maturation of hippocampal injury would be expected to occur. Because normoglycemic rats subjected to the same insult survived 7 days and were found to have 100% hippocampal CA1 damage, it is likely that the ischemic insult alone was sufficient to cause maximal glutamate accumulation, disallowing any further augmentation by hyperglycemia. This could be confirmed in future studies by repeating the experimental protocol with a shorter duration of ischemia, which would result in only moderate damage in the CA1 sector in normoglycemic rats.

The results of this work by Li et al are consistent with the hypothesis that hyperglycemia worsens ischemic outcome, at least in part, by augmenting extracellular glutamate accumulation, which in turn upregulates N-methyl-D-aspartate receptor activation and conductivity to calcium. However, data to date remain only correlative. The importance of this limitation can be demonstrated by examining effects of hypothermia on glutamate concentrations during ischemia. It is known that hypothermia nearly abolishes any increase in glutamate concentration.5 However, recent evidence provided by Yamamoto et al6 questions the importance of this effect. When hypothermic gerbils underwent microinjection of glutamate into hippocampal CA1 in sufficient quantity to cause intraschismic extracellular glutamate concentrations to be similar to those observed in normothermic gerbils, hypothermia still caused a profound reduction in histological damage. Accordingly, additional work is required to confirm a causal relationship between hyperglycemia and glutamatergic excitotoxicity. Because NMDA receptor activation is associated with increased permeability of calcium, assessment of calcium transients in normoglycemic versus hyperglycemic animals would be important. Also, because glutamate excitotoxicity has been linked to opening of the mitochondrial permeability transition pore,7 investigation of mitochondrial responses to hyperglycemic versus normoglycemic ischemia should be examined. The results of Li et al justify further pursuit of these questions.
