Racism and tPA Use in African-Americans

To the Editor:

The investigation of Johnston et al1 into the influence of ethnicity on thrombolysis raises the spectre of racism in health service provision. However, as shown in the case of cardiac catheterization after myocardial infarction, racism is not always the reason for differences in treatment.2

Although the authors used a simple dichotomous definition of stroke severity in their regression analysis, they did not account for stroke subtype (or National Institutes of Health Stroke Scale [NIHSS] score). The proportion of ischemic stroke due to small-vessel disease in African-Americans is 52% compared with 25% in whites.3 Lacunar strokes tend to be less severe (maximum NIHSS of 10) and have a better prognosis than cortical ischemic strokes.4 The authors’ Table 2 demonstrates that despite American Heart Association guidelines, physicians are reluctant to give tPA to patients with less-severe stroke (only 8% of all eligible patients). Furthermore, physicians may not offer thrombolysis to those with suspected small-vessel stroke on pathophysiological grounds.5 This is in spite of no differential effect found in the NINDS study6 and that initial lacunar syndromes poorly predict eventual lacunar stroke.7

White patients arrived in the emergency department sooner than African-Americans. Although the percentage arriving within 3 hours was similar, a more realistic criterion for eligibility would be 2.5 hours, given that imaging, examination, and consent to treatment must all be completed prior to administration.

Another possible explanation is mistrust of health services. Even a few minutes’ prevarication can result in the 3-hour time window being exceeded. This may not be recorded as a refusal of treatment.

As one of the few centers outside the United States offering thrombolysis to a population with a high proportion of Afro-Caribbean patients, we have encountered the above problems, which cannot be attributed to racial prejudices. Racism in medicine, whether conscious or subconscious, individual or institutional, is to be deplored. However, ethnic variation in pathophysiology and behavior should be thoroughly examined before assuming that racism is the explanation for observed differences.

Response

The causes of disparities in healthcare delivery—including the use of tPA in ischemic stroke—are likely to be complex, as suggested by Dr Evans and colleagues. In our article, we never imply that racism is the only cause of the ethnic disparity in tPA delivery. However, we do suggest that it contributed to the disparity, and appreciate the opportunity to clarify our reasoning.

We doubt that stroke subtype contributed importantly to the disparity. We know of no evidence to suggest that small-vessel strokes are responsible for a significantly larger portion of ischemic strokes in blacks. In fact, the article referenced by Evans and colleagues appears to report that small-vessel strokes account for 21% of ischemic strokes in blacks and 17% in whites—a difference that is neither clinically nor significantly important. Findings were similar in Northern Manhattan.2

Stroke severity was an important predictor of tPA use in our study, and a more detailed analysis would have been interesting. However, we found no difference in the portion with severe strokes (blacks 18% versus whites 16%), and others have found that outcomes are worse after ischemic stroke in blacks.3 Timing also does not appear to account for the disparity in our study. When we limited analysis to those arriving within 2 hours, black tPA candidates were still less likely to receive tPA than white candidates (8% versus 24%; P = 0.04).

We agree that mistrust of the medical system may have contributed to the disparity. Though no black patient was documented to decline tPA, it is possible that documentation was incomplete. Of course, some may postulate that mistrust itself is rooted in racism.

When are data adequate to raise the possibility that racism is contributing to a disparity in healthcare delivery? Should we require more solid proof of racism than other factors, such as age or insurance type? The answer must depend in part on the consequences of being wrong: What are the implications of suggesting that racism is a contributor to a disparity when it is not? Regardless of cause, taking greater care in offering tPA to blacks with ischemic stroke may reduce a very large disparity in its use at minimal additional cost.

Re: Utilization of Intravenous Tissue-Type Plasminogen Activator for Ischemic Stroke at Academic Medical Centers

To the Editor:

We write in response to the recent significant article of Johnston et al. The authors’ hypothesis is that racism, even on an unconscious level, may contribute to the disparity between administration of tissue plasminogen activator (tPA) to blacks and the administration of tPA to whites for acute ischemic stroke at academic medical centers in the United States.

While we do not dispute their findings, we wish to introduce an additional point that was not considered in their article, and to forward a means to partially remedy the disparity. Their findings were based on a retrospective analysis at 42 academic medical centers in the United States. tPA may have been administered at some of these institutions under the auspices of a phase II or III clinical study. If so, a community consultation should have been performed prior to this emergent research, per FDA and NIH requirements. However, the community consultation requirement has not been appropriately explained by the FDA or the NIH, and researchers may be at a loss as to how to effectively inform the community that experimental treatments are being administered without consent of either the patient-subject or a surrogate.

If physicians knew that an effective community consultation had been performed, one that reached all segments of the community, they would be less likely to unconsciously bias themselves against administering experimental treatment to minority populations. The specter of unethical research may account for some of the unconscious bias against administering experimental therapies to populations that have experienced historical injustices in clinical research. Rather than discriminating on the basis of racism, physician-researchers may be overly cautious in administering experimental therapies. Knowledge that an effective community consultation had taken place may allow physician-researchers to confidently administer experimental, albeit potentially lifesaving, treatments.

Johnson et al may have told us something we already knew: more work needs to be done to determine what counts as an effective community consultation before emergent research, if so, a community consultation should have been performed prior to this emergent research, per FDA and NIH requirements. However, the community consultation requirement has not been appropriately explained by the FDA or the NIH, and researchers may be at a loss as to how to effectively inform the community that experimental treatments are being administered without consent of either the patient-subject or a surrogate.

The authors are currently performing research on effective community consultations prior to emergent research, supported by Summa Health Foundation.

Response

tPA was approved for use in patients with ischemic stroke for 3 years prior to the study period, and the initial study proving its efficacy was not performed in most of the communities studied. Therefore, we cannot comment on the potential effect of community consultation. However, we agree in principal that informing communities about the use of tPA for stroke could reduce underutilization in all ethnic groups.

Life-Threatening Complications From Spinal Manipulation Are Rare

To the Editor:

The letter by Dr Ernst is misleading from the title. Are long thoracic nerve palsy and “local discomfort” life-threatening? The estimated annual incidence of spontaneous vertebral artery dissection (VAD) is 1 to 1.5 cases per 100,000. Estimates of cerebrovascular events associated with cervical manipulation range from 0.1 to 5.0 per 100,000. These are estimates of events and do not extrapolate to deaths or permanent impairment, which is an even smaller percentage that would be considered “life-threatening.”

In contrast, the risk of stroke from pregnancy is between 26 and 69 per 100,000. “Iatrogenic” arterial dissection as a complication of cerebral angiography has an “underreported” incidence rate of 400 per 100,000. “Spontaneous” VAD can be caused by innocuous movements and one would wonder whether the reports of manipulation being involved in VAD are just reports of the same entity. The concept of “spontaneous” lends to an idea of “instantaneous,” further confusing to etiology of this disease entity when manipulation is involved.

While some stress the temporal coincidence of trivial movements/chiropractic care with the onset of cerebral artery dissection, easily concluding cause, suspicion should be raised with the discrepancy between relatively minor forces resulting in such severe vascular lesions.

An underlying arteriopathy leading to weakness of vessel walls and predisposing patients to “spontaneous” and/or chiropractic dissections has been proposed. In a rare autopsy examination after manipulation, the histopathological study by Peters et al of cervical arteries revealed widespread underlying disease of the arteries, with focal and segmental degeneration of smooth muscle tunica media and cystic transformation of the vessel walls. Additional predisposing factors were also described.

It would appear to be of more benefit to the public if articles identified the genetic, environmental, and maladaptive factors, rather than hyping the rare life-threatening complications of chiropractic care.

Dr Di Duro’s interest is much appreciated. In my view, however, his arguments are of debatable validity. Firstly, my editorial1 did discuss many life-threatening complications and also included, for the sake of completeness, some minor adverse events. Thus, I do not feel that the title was misleading. Second, estimates of cerebrovascular accidents (CVAs) after spinal manipulation may well be invalid. They are built on certain assumptions regarding the level of underreporting. We have recently shown that, in the United Kingdom setting, underreporting seems to be 100%.2 This renders estimates hardly worth the paper they are printed on. Third, a recent, large case-control study has demonstrated that spontaneous and chiropractic-induced CVAs are, in fact, not the same.3 At least some populations seem to be at risk of suffering a CVA from chiropractic spinal manipulation which is significantly above that of spontaneous CVAs.

In essence, this leaves us with the following situation. There is precious little hard evidence that upper spinal manipulation produces significant health benefits for any type of patient. There is mounting evidence that these procedures are associated with relevant risks. Thus, there is considerable uncertainty regarding the risk benefit profile of upper spinal manipulation. It is now up to the chiropractic profession to convincingly demonstrate that the benefits outweigh the risks. Until such data are available, it is legitimate, I would even say prudent, to be cautious and critical—primum non nocere!

Retinal and Cerebral Artery Embolism After “Shiatsu” on the Neck

To the Editor:

We read with great interest the articles by Ernst4 on the life-threatening complications of spinal manipulation and by Rothwell et al5 on the relation of chiropractic manipulation and stroke, as we recently experienced a case of serious complication caused by acupressure “shiatsu” on the neck. With the great demand throughout the industrialized world for complementary and alternative medicine, not only chiropractic and spinal manipulation but also shiatsu, an oriental technique of massage, are becoming increasingly popular in western countries as a support for general health and well-being.6,7 There are many acupuncture points on the body surface for shiatsu known as “tsubos,” and it is accepted that by applying pressure on these tsubos one can achieve physically healing effects with hardly any serious side effects.8 There are two such tsubos on the nape, and shiatsu on these is known to improve tension headache due to neck and shoulder stiffness; however, we recently experienced a very suggestive complication of shiatsu on these tsubos.

Transient ischemic attack was diagnosed in an 80-year-old man after he experienced a sudden onset of weakness in his left hand in December 1999. Although he was asymptomatic on admission, MRI demonstrated a small infarction in the right frontal lobe. MR angiography demonstrated bilateral internal carotid artery stenoses just distal to the carotid bifurcation. Cerebral angiography with contrast media was not performed at that time due to mild renal impairment. After anticoagulant therapy with argatroban for 7 days, he was discharged, free of any neurological symptoms, with a prescription for ticlopidine hydrochloride. On the evening of the day of discharge, he received shiatsu massage on the neck in a prone position, with his face buried in a pillow, for approximately 10 minutes to improve a mild headache associated with neck and shoulder stiffness. Immediately after rising, he was aware that the nasal half of his right visual field was impaired. When this ocular symptom did not improve, he returned to our hospital the following morning. Ophthalmologic examination disclosed that his right visual acuity was only counting fingers at 10 cm, and neurological examination showed slight left hemiparesis dominant in the upper extremity. Fundus examination disclosed diffuse retinal edema with multiple emboli in many branches of the central retinal artery, and fluorescein angiography was compatible with multiple branch occlusions of the central retinal artery (Figure, left). Fluid-attenuated inversion recovery MRI of the brain showed multiple small infarctions in the right frontoparietal lobe (Figure, right). The patient was hospitalized and treated with intravenous infusion of urokinase for 7 days, with almost full recovery of left hemiparesis and minimal improvement of ocular symptoms.

As Ernest1 mentions, it is important to generate reliable incidence figures on complications of spinal or chiropractic manipulations. The same holds true for shiatsu; however, very few serious complications of shiatsu therapy could be found in the literature. Mumm et al6 reported an interesting case of probable traumatic zoster that might have resulted from direct trauma to the nerve or nerve roots during shiatsu massage. On the other hand, direct pressure to or around the extracranial carotid artery, such as carotid sinus massage, can cause embolic accidents, especially in elderly people.7 It would not be unexpected that shiatsu on the neck could cause similar complications; however, we were unable to find any medical reports of cerebral or retinal artery embolisms directly caused by shiatsu. We are not denying the traditional healing effects of shiatsu, but we would like to call to attention the fact that it may cause serious neurological symptoms in patients with atherosclerotic extracranial carotid artery disorders, the incidence of which is greater in Caucasians than in Japanese,8 and the potential risk of embolic accidents associated with shiatsu may be higher than generally accepted. Although Rothwell et al5 successfully demonstrated objective data on the association of vertebralbasilar accidents and chiropractic manipulation by a population-based case-control study, they mention that the rarity of vertebralbasilar accidents makes this association difficult to study. The same problem can be predicted when studying the association between shiatsu and embolic accidents originating in the extracranial carotid artery. However, it should be stressed that these complications can be avoided if patients at high risk are properly informed beforehand of the potential association between embolic stroke and manipulation on the neck.

Is Retrospective Study Reliable in Genetic Studies?

To the Editor:

We read with great interest the preliminary study by Niskakangas et al.1 “Association of Apolipoprotein E Polymorphism With Outcome After Aneurysmal Subarachnoid Hemorrhage.” Although in this paper the authors concluded that there is a significant association between apolipoprotein E e4 (apoE e4) and the outcome of subarachnoid hemorrhage (SAH) patients, we have some reservations about the methodology and its data analysis.

The classification of CT findings used in this study was different from the original study of Fisher et al:2 there are only 4 grades in Fisher’s grading scale, instead of the 5 grades shown in the article by Niskakangas et al. Each grade was clearly defined in the Fisher study, whereas the scale used in the Niskakangas study falls short of a clear definition. In their statistical analysis section, the authors then mention that the CT findings were allocated to 1 of the 4 categories. It would be helpful if the authors could clarify how they grouped the 5 grades into 4 categories during the statistical analysis.

We noticed there was a fundamental problem with the data collection and presentation on the neurological outcome of patients. Patients from groups both with and without apoE e4 had a 0- to 57-month follow-up. This may contribute to inaccuracy and bias in the assessment of the patients neurological outcome after a SAH. The convention in neurological outcome assessment prescribes a duration of at least 6 months from the time of hemorrhage to the time of assessment, in order to ensure that the patient’s clinical condition and recovery are stable before assessment.3 Information on the distribution (SD) of the duration of follow-up may indicates the proportion of patients who had their neurological outcome assessment too early during their recovery period. The other possibility is that these 0-month follow-up cases were all mortalities.

Results presented in Tables 1, 2, and 3 of the article by Niskakangas et al may contain an error. All variables, including the demographic, clinical, and radiological data and the neurological outcome, that compared with the apoE e4 group were not carried out by the Fisher exact test as mentioned in the Statistical Analysis section. The probability values presented were, in fact, the standard errors of the difference of the 2 proportions compared; neither the scale of measurement was comparable (eg, 0.029 instead of 2.9%) nor was the calculation was based on the exact method.

Apart from the misleading probability value calculated, it was inappropriate to compare each subgroup separately. For example, the authors compared each level of initial Hunt and Hess score with and without apoE e4 separately using the same data. Instead, the Fisher exact test (or χ² test), as originally proposed, for this 5×2 contingency table is the appropriate method.

The authors mentioned that there were 4 patients who were dead, but their apoE genotypes were unknown. We have also included these patients into the analysis, assuming that none, 1, 2, 3, or all 4 harbor the apoE e4 allele. The association between apoE e4 and outcome disappeared when none of these patients were assumed to have the gene (P=0.068; OR 2.15, 95% CI 0.94 to 4.97).

This article clearly demonstrated the limitation of a retrospective study. It is difficult to convince the readers that there is an association between APOE polymorphism and SAH recovery with a retrospective study as shown in this paper, especially when there was a significant number of missing patients (14.3%). Although we have queries regarding the methodology, data analysis, and the conclusion of this article, it did demonstrate the necessity of having a well-designed prospective clinical study that may be in a better position to investigate the association.

Response
We wish to thank Poon et al for their interest and very valuable comments concerning our recent article in Stroke.1 We agree that we did not use the original Fisher’s grading scale, but properly noted that a modified Fisher scale was used. We should have defined the grading system more clearly already in the article. Differences are as follows: in grade 1, we saw only a very small amount of blood locally in the subarachnoid space (can be seen); in grade 2, there was subarachnoid blood <1 mm thick; grade 3, >1 mm thick, diffusely spread throughout the subarachnoid cisterns; and in grade 4, there was diffuse subarachnoid hemorrhage (SAH) and/or large hematoma or intraventricular bleeding. Although we did not use the original Fisher grading scale, in our opinion it was mainly based on that, and therefore we considered it fair to reference the original article. Regrettably, there is an error in the text in the Statistical Analysis section. We have allocated CT findings to 5 groups in statistical analysis, 0 through 4.

We agree that there is heterogeneity in the follow-up times of the patients. However, the length of the follow-up time partly describes the outcome of a patient, and the different distribution of the e4 allele is already seen here. Patients with good outcome returned to normal life after a convalescence period of approximately 2 to 3 months, were clinically stable, and had no clinical indication to be followed up after that. Patients who were primarily in poor condition were followed up for a longer period, enabling us to better estimate the final clinical condition of these patients. The majority of those 0-month follow-up cases were patients who died, and in addition 3 patients (followed up for 1 to 2 weeks) who were primarily in good condition when leaving the hospital.

As Poon et al point out, there were unforgivable calculation errors concerning the statistics of the patient characteristics (Table 2). The probability values in the Table 2 are erroneous statistical raw data. The differences between the patients with and those without the APOE e4 allele were tested using the χ² test. All probability values for the group differences were statistically insignificant, as follows. In the Table 2, concerning the initial Hunt and Hess score, the P value was 0.21 (df=4, χ²=5.82), and in the initial CT findings the P value was 0.91 (df=4, χ²=0.97).

Poon et al have presented an interesting view about considering those 4 missing dead patients, presenting 3% of the whole series. That was very valuable point, and it emphasizes the problem of the selection bias in retrospective association studies. We hypothesized that the e4 allele is a risk factor for poor outcome after SAH. In a recent publication by Dunn et al,2 the e4 allele frequency of SAH patients was lower than in normal population, suggesting that the e4 allele could be associated with an excess rate of early mortality after SAH and therefore causing a selection bias, while patients with poor outcome are not included to clinical patient series. The same could have happened in our series.

Poon et al have stated some of the potential weaknesses of retrospective study design in genetic studies in general and in our study in particular. The complexity of the natural cause of this devastating disease and possible complications in therapy itself make the design of outcome studies quite difficult. Thus far, there has been one prospective clinical series studying the association of APOE genotype with SAH outcome, and even in it there were some problem with selection bias.

We do not suggest that our hypothesis is the final truth. It is a preliminary report, as we stated in the subtitle of our article. There is, indeed, a need for a prospective, properly designed population-based studies that includes patients who die before admission to hospital. Future studies will show whether the APOE gene polymorphism has a role in the prognosis of subarachnoid hemorrhage. Considering the fundamental role of APOE in neurobiology,3 we think that APOE is an important area for studies of subarachnoid hemorrhage and of hemorrhagic stroke in general.

To the Editor:
I would like to respond to an article published in a recent issue of Stroke, entitled “Is Carotid Intima-Media Thickness Useful in Cardiovascular Disease Risk Assessment?”1

The title of the article caught my eye because my profession involves extensive use of carotid intima-media thickness (CIMT) for detection of atherosclerosis. However, I was surprised that the title did not reflect the misleading nature of the article, and it appears to refute the authors’ earlier published works.2

The title of the article suggests that certain cardiovascular risks were compared with assessment of CIMT. The authors of this article concluded that as a screening tool, CIMT does not represent a substantial increase in the predictive value for
cardiovascular events. Moreover, there was an inference that CIMT cannot be used alone as a screening tool. I must completely disagree. The article described the Rotterdam Study, in which investigators used CIMT as a screening tool in an elderly population. This was a select population that would have additional risk factors present. The question should have been raised as to whether exclusive use of CIMT in a younger population with risk factors is able to identify the presence of cardiovascular disease in its earliest stages. Even comparing two distinct population groups would yield a more meaningful result. CIMT is not appropriate for screening when the patient would have known cardiovascular disease risk factors in development.

The key to controlling the disease is prevention, rather than dealing with it after it has progressed to riskier stages. A typical screening setting is for new patient discovery, and the methodology for screening was not optimal here. Unlike other screening methods, the purpose of CIMT is to look at the disease itself, instead of examining the risk factors. Risk factors are often arbitrarily selected by the investigator out of a pool of sometimes more that 246 suggested factors in every patient. In a different Netherlands study, a major risk factor like elevated cholesterol levels has been demonstrated by Sijbrands et al not to limit normal lifespan in 40% of the cases studied. Would this imply that the authors review more current methods for detection. We remain confident that our ounce of prevention is better than nothing in a screening setting, as well as a risk factor management setting. Our procedure allows us to predict with a high degree of confidence both an absolute and relative risk of cardiovascular complication in ethnically diverse population groups.

In short, the eye-catching title does not cover the content of the article and disagrees with both current practice of this unique tool in cardiovascular management. Utilization of modern CIMT for screening in the appropriate population is a more effective tool than other methods for detecting the presence of cardiovascular disease in its earliest stages. This gives better opportunity for treatment and possible reversal of cardiac disease. I would suggest that the authors review more current methods for utilizing CIMT as a screening tool in cardiovascular disease detection. We remain confident that our ounce of prevention is worth a pound of cure.

Jacques D. Barth, MD, PhD, FACC
Southern California Prevention and Research Center
Encino, California

6. Barth JD. Which tools are in your cardiac workshop? Carotid ultrasound, endothelial function, and magnetic resonance imaging. Am J Cardiol. 2001;87:8A–14A.

Response
Our article on the usefulness of carotid intima-media thickness measurements in cardiovascular risk assessment concluded that in a general population aged 55 years or older, when information on established risk factors (medical history, smoking, blood pressure, cholesterol, and body mass index) is available, the measurement of CIMT does not add substantially in distinguishing high-risk from low-risk patients. When, however, only age, sex, and CIMT were presented, there was a considerable increase in the diagnostic ability of the model. We agree with Dr Barth that our data pertain to subjects 55 years or older, and it may be different in younger populations and in high-risk populations. We disagree, however, that such measurements have no value in patients in which disease has progressed to some extent. Even in those at higher risk of coronary heart disease it may be of great importance to be able to identify those who are at a relative higher risk compared with those at a relative lower risk in order to target treatment.

Instead of an arbitrary selection out of 246 risk factors, as Dr Barth suggested, our selection of established risk factors was based on the ability for a general practitioner to easily obtain that information, since in the Netherlands the general practitioner is usually the first line of the medical circuit to contact. The focus of our study was to evaluate the added value of the CIMT measurement when added to easily obtainable risk factors.

With respect to the CIMT measurement as performed in the Rotterdam Study, Dr Barth is of the opinion that we used an outdated measurement technique and that an aggregate maximum measurement of CIMT is also outdated. We would like to point out that the CIMT measurement technique used in the Rotterdam study is based on manual tracing over a 10-mm segment as well as on an automated edge technique that has been shown to be state of the art and is used in trials and population-based studies. Furthermore, we disagree with the “outdatedness” of aggregate measures. Clearly, the far wall of the common carotid is perhaps easier to measure and may yield a high reproducibility, but the aggregate measures reflect the entire carotid atherosclerosis burden and are and will remain a major outcome in trials.

Finally, our CIMT measurement predicts future disease in a magnitude similar to that in other population-based studies that use either manual tracings or automated edge detection tracing.

M.L. Bots, MD, PhD

increased correlation between soft plaques and episodes. The reasoning that there may likely exist some kind of cerebral episodes as well in the operation that many embolic episodes do not provoke many moniae in infection and plaques (soft, or not taking under consideration) is that a correlation probably exists between infection from C pneumoniae and plaques can be influenced by C pneumoniae infection, because wherever we find C pneumoniae infection we would have been more likely to be associated with embolization and II with the symptomatic patients, the majority of the symptomatic patients had plaques of the III, IV, and V type. The basic conclusion is that there was a high affinity between recent disease and signs of C pneumoniae in the plaques when PCR was used. In our work, we concluded that the symptomatic patients, in the majority of the cases, were seropositive.

In any case, there is no etiological connection between the systematic disease arising from C pneumoniae , as shown by the titer of the antibodies, and the specific localization on the carotid plaque.

More studies focused on this matter might connect the titer of the antibodies and carotid stenosis, or, better still, the influence of the ratio in the presence of cerebral episodes.

Re: Chlamydia pneumoniae Does Not Influence Atherosclerotic Plaque Behavior in Patients With Established Carotid Artery Stenosis

To the Editor:

We read the interesting paper of Gibbs et al.1 We believe that, just as in other cases, the inflammatory response to infection probably plays a significant role.2 The basic incentive in writing this letter is to underline the following assertion that results from the original idea of the authors to check the rhythm of emboli by means of transcranial Doppler ultrasonography (TCD).

The fact that most patients without Chlamydia pneumoniae infection present with a cerebral episode does not discard the relationship between infection from C pneumoniae and embolization. It is simply the reporting of the results, which the authors suggest, that the plaques can be influenced by C pneumoniae infection, because wherever we find C pneumoniae infection we discover more embolic episodes.

The conclusion which results from the interpretation of Table 2 of Gibbs et al (although not documented in our experience, however) is that a correlation probably exists between C pneumoniae infection and plaques (soft, or not taking under consideration that many embolic episodes do not provoke many cerebral episodes as well in the C pneumoniae–positive group), despite the fact that the discovery of the rhythm of emboli with TCD had not resulted in an increase in the number of cerebral episodes. The reasoning that there may likely exist some kind of increased correlation between soft plaques and C pneumoniae infection results from the interpretation of the table. More investigation of the carotid plaque with ultrasonography is required, however, with an adjunct TCD, for better corroboration of the final result.

In our work, an attempt was made to combine the recent or chronic disease due to C pneumoniae, as shown from the results of the titers of immunoglobulin (Ig)G and IgM. Our results were as follows3,4: 20 of 35 (57.1%) of the patients had an increased IgG titer of antibodies; 2 patients had high IgG and IgM antibody titers and were PCR positive, while both were symptomatic. It should be noted that we had also examined samples of thyroid artery in all of the patients in whom C pneumoniae was not traced in the arteries. Sixty-five percent of the 20 patients with increased IgG antibody titer were symptomatic; in the subgroup of 8 patients with IgG and IgM antibodies (recent disease), 85% were symptomatic; and in the subgroup with active disease (IgG+IgM+polymere chain reaction [PCR]), both patients were symptomatic. Moreover, we examined the quality of the atheromatous plaque with use of color-coded duplex sonography; however, we were not able to connect the soft plaques of type I and II with the symptomatic patients, while the majority of the symptomatic patients had plaques of the III, IV, and V type. The basic conclusion is that there was a high affinity between recent disease and signs of C pneumoniae in the plaques when PCR was used. In our work, we concluded that the symptomatic patients, in the majority of the cases, were seropositive.

In the recently article by Jonsson and Asplund, the authors demonstrate that statins have a moderate effect in improving the prognosis of ischemic stroke patients, underlying the possible complex role of statins in determining prognosis after ischemic stroke. Their data are in agreement with our preliminary results on the concurrent use of statins in patients with first-ever ischemic stroke. Previously, we found that the use of statins reduces the levels of C-reactive protein (CRP) after ischemic stroke, the initial neurological deficit, and improves the prognosis of stroke patients with a significant reduction of the 1-year risk of death or new vascular events. Recently, we have extended these observations in the same ischemic stroke cohort that had concluded the 2-year follow-up. All patients (n = 193) were recruited in the period between March 1, 1998, and March 31, 1999. Design, methods, and baseline characteristics of our stroke data bank have been previously reported. We measured levels of CRP after stroke (within 24 hours), at 3 months, and at the end of the 2-year follow-up, together with total cholesterol, HDL and LDL subfractions, and triglycerides. Differences in proportions were evaluated by $\chi^2$ test. Continuous variables are described as mean $\pm$ SD or median values with 25th and 75th percentiles, and comparisons between groups were evaluated with the Student test or Mann-Whitney $U$ test, when appropriate. The Kaplan-Meier technique (log-rank test) was applied in survival analysis. Log-normalized values of CRP were used to evaluate correlations over time.

At the entry, mean total cholesterol concentrations were 4.62 $\pm$ 1.25 mmol/L in men and 5.31 $\pm$ 1.06 mmol/L in women ($P = 0.001$; Student's test). Mean HDL cholesterol concentrations were 0.95 $\pm$ 0.39 mmol/L and 1.02 $\pm$ 0.31 mmol/L ($P = 0.1977$), mean LDL cholesterol concentrations were 3.97 $\pm$ 1.32 mmol/L and 4.64 $\pm$ 1.06 mmol/L ($P = 0.001$), and mean triglycerides concentrations were 1.50 $\pm$ 0.73 mmol/L ($P = 0.0255$), respectively. Median CRP concentrations were 1.85 mg/dL in men (0.70 to 5.40) and 1.0 mg/dL in women (0.23 to 2.65; $P = 0.0020$; Mann-Whitney $U$ test) at the entry. Ninety-three patients (48.2%) had a total cholesterol concentration $\geq$ 5.0 mmol/L at the time of ischemic stroke, 122 (63.2%) had a ratio of total cholesterol to HDL cholesterol $\geq$ 5, and 175 (90.7%) had LDL cholesterol $\geq$ 3.0 mmol/L. Fifty-two patients (26.9%) took statins: simvastatin (n = 37; dose range 10 to 20 mg/d), pravastatin (n = 10; range 20 to 40 mg/dL), and atorvastatin (n = 5; range 10 to 40 mg/dL) at the time of qualifying stroke; of these only 16 (8.3%) had a total cholesterol concentration $<$ 5 mmol/L.

Younger age (70.5 $\pm$ 9.8 versus 73.7 $\pm$ 8.8 years; $P = 0.0321$, Student's $t$ test), a greater prevalence of arterial hypertension (90.4% versus 68.8%; $P = 0.0022$, $\chi^2$ test), and history of dyslipidemia (51.9% versus 31.2%; $P = 0.0081$) were noted in statin group. Significantly lower median levels of CRP (0.6 mg/dL [0.3 to 1.5] versus 1.9 mg/dL [0.8 to 3.75]; $P < 0.0001$, Mann-

Whitney U test) within 24 hours after stroke, together with a significantly lower score on the Canadian Neurological Stroke Scale (7.5 [6.0 to 9.0] versus 6.0 [4.5 to 8.0]; P = 0.0003) were also found in patients with statin therapy. No differences were found in terms of neuroradiological findings such as large infarcts, cortical involvement, hemorrhagic transformation, brain edema, or of stroke subtypes.

There was not a compulsive lipid-lowering treatment during follow-up, so only an additional 7 (3.6%) patients received statin treatment in the lower tertile but only 4 in the highest tertile. The absolute differences in risk between tertiles of CRP were 9.4%, 24.6%, and 28.2%, respectively. To prevent 1 death or any new vascular event: 36 patients died at 2-year follow-up period, 76 patients (40%) had a combined end point (death or any new vascular event): 36 patients died (vascular death in 29, and 40 had a nonfatal vascular event (cardiac in 21 and cerebral in 19). Only 12 combined end point (3 death and 9 new non fatal vascular events) were registered in patients with statin therapy (20.3% versus 47.8%, P = 0.0004, log-rank test). The Figure shows the cumulative risk at 2-year of those without statin therapy, median CRP levels and the mean change in CRP at 2-year between patients with and without statin therapy in the 2 groups at the end of 2-year follow-up. However, there were no significant differences in the 2 groups in terms of median CRP levels (difference, −15%; P<0.0001; mean changes −0.09 mg/dL; P = 0.016). Thus, statistically significant differences were found at 2 years between patients with and without statin therapy in terms of median CRP levels (difference, −78.6%; P = 0.0017), mean CRP levels (difference, −34.7%; P = 0.028), and absolute mean change in CRP (difference, −0.15 mg/dL; P = 0.031).

In conclusion, the proportion of patients with ischemic stroke who received statin treatment is low, and even an even lower proportion of them received efficacious control of hypercholesterolemia. A more extensive and aggressive use of statins in all patients at risk for and with first-ever ischemic stroke, and especially in patients with persistently higher CRP levels after ischemic stroke, should be developed into specific screening programs that will be appropriately funded and developed in a public health perspective.
