Seasonal Distribution of Antiphospholipid Antibodies

Thanh-Ha Luong, MD; Jacob H. Rand, MD; Xiao-Xuan Wu, MD; James H. Godbold, PhD; Mayra Gascon-Lema, MS; Stanley Tuhrim, MD

Background and Purpose—The purpose of this study was to determine if there was a seasonal variation in antiphospholipid antibody (aPL) titers and whether this variation differed between stroke cases and control subjects.

Methods—IgG and IgM anticardiolipin and antiphosphatidyl serine antibody titers were obtained on serum samples from 884 stroke patients and 1024 control subjects over a 7-year period. Temporal distributions by month of blood draw were evaluated.

Results—Marked seasonal differences in the proportion of positive titers were found for control subjects, but no seasonal variability among patients was noted. In control subjects, positive titers occurred less frequently in the summer months, mirroring the seasonal trends seen in respiratory track infections and rheumatic fever.

Conclusions—Our data suggest some aPL antibodies arise from different origins in patients and control subjects. The seasonality observed in the apparently normal population may be related to antibodies of infectious origin and is consistent with the reported lack of association with thrombosis of infection-related antibodies. (Stroke. 2001;32:1707-1711.)

Key Words: antibodies, anticardiolipin • antibodies, antiphospholipid • phosphatidyl serines • stroke • seasons

Antiphospholipid antibodies are a heterogeneous family of antibodies that react to negatively charged phospholipids or phospholipid-protein complexes. Currently, they are detected by either ELISA, with anionic phospholipids used as the antigens (eg, anticardiolipin antibodies, antiphosphatidylserine antibodies), or by the ability to prolong coagulation time in a phospholipid-dependent assay (lupus coagulant).1,2 Antiphospholipid (aPL) antibodies are an element of the antiphospholipid syndrome, a condition characterized by arterial and venous thrombosis, recurrent fetal loss, and thrombocytopenia in the presence of aPL antibodies.3 There also appears to be an association between aPL antibodies and ischemic events even in the absence of the other features of the syndrome.4 Progress has been made in the last decade in describing mechanisms of action of aPL antibodies. However, the pathogenesis of aPL antibodies and the precise mechanisms by which they promote thrombosis remain unknown.5,6 The association between aPL antibodies and autoimmune disease has long been recognized, but more recently it has also been suggested that infection may trigger the generation of aPL antibodies by exposure of antigenic phospholipids, which induce immunologic responses.7-10 However, it has been suggested that infection-induced aPL may not be thrombogenic. Because many infections tend to follow a seasonal pattern, we decided to investigate the seasonal distribution of aPL antibodies among patients with acute stroke and community-based control subjects, reasoning that the risk associated with these antibodies may also demonstrate seasonal variability.

Subjects and Methods
This study is an analysis of data from a subset of cases and control subjects in the previously described Minorities Risk Factor and Stroke Study (MRFASS).11 The present report includes 869 patients ≥45 years of age who were admitted to Mount Sinai Hospital or its affiliate, North General Hospital, New York, between November 1991 and November 1998, with an ischemic stroke of <5 days’ duration. All patients were examined by a study neurologist and had CT or MRI as part of their evaluation. Informed consent was obtained either from the patient or proxy. Control subjects were 1024 individuals ≥45 years of age with no history of stroke, recruited from among residents of the hospital’s catchment area between January 1992 and May 1995. Control subjects were group-matched by ethnicity in a ratio of approximately 2:1 for blacks and Latinos and 1:1 for white, non-Latinos. Age and sex were not used for matching. A full description of the study methodology and baseline characteristics of the study population have been published previously.11

Serum Samples
Blood samples were obtained from the patients on the morning after admission and from the control subjects on the morning of the study visit. All serum samples were frozen within 2 hours of collection and stored at −70°C until tested for aPL antibodies. Participants’ samples were measured for anticardiolipin (aCL) antibodies from the start of the study and antiphosphatidylserine (aPS) antibodies since November 1995 when the aPS assay became available in the study hospital.

Laboratory Methods
Anticardiolipin antibodies and aPS antibodies were measured by ELISA, with the use of commercial kits (REAADS Medical Prod-
ucts, Westminster Co). The assays were performed as follows: Sera were diluted 1:50 with sample diluent, which contained a standardized concentration of β₂-glycoprotein I (β₂-GPI). Then 100 μL of the diluted sera was distributed to each well of microtiter plates coated with cardiolipin (or phosphatidylserine) in duplicate. After a 15-minute incubation at room temperature, the wells were washed 4 times with PBS, pH 7.4, to remove the unbound serum proteins. Then, 100 μL of solutions containing goat antibodies specific for human IgG or IgM labeled with horseradish peroxidase were added to the wells. After another 15 minutes of incubation at room temperature and washing 4 times with PBS, 100 μL of substrate solution containing tetramethylbenzidine and hydrogen peroxide as the chromogenic substrate were distributed to the well. After a 10-minute incubation at room temperature, 100 μL of stopping solution (0.36N sulfuric acid) was added to the wells. Within 30 minutes after the addition of stopping solution, the optical density was read in a microplate reader (Molecular Devices kinetic microplate reader) with a dual beam at 450-nm and 650-nm wavelength.

The results of IgG and IgM anticardiolipin antibodies (aCL IgG, aCL IgM) were expressed in GPL or MPL units. One GPL unit is equivalent to 1 μg/mL and 1 MPL unit is equivalent to 1 μg/mL of affinity-purified IgG and IgM sera, respectively. In the same concentration of purified sera, the values of antiphosphatidylserine antibodies (aPS IgG, aPS IgM) were expressed in GPS or MPS units. The results were defined as positive if they were >23 GPL or >11 MPL for aCL antibodies and >16 GPS or >22 MPS for aPS antibodies, according to the instructions of the manufacturer.

### Statistical Methods

The χ² test was used to compare the difference in prevalence of stroke risk factors between patients and control subjects. The differences between cases and control subjects in geometric mean aPL titers were assessed by using a t test (Satterwaite method for unequal variances) on log-transformed data. The effect of season and case-control status and the interaction of these variables on the log transformation of the geometric mean titers of each aPL antibody were assessed with a 2-way ANOVA. The χ² test developed by Walter and Elwood12 was used to evaluate the seasonal trends of positive aPL antibody variation. Odds ratios with 95% confidence intervals were calculated by logistic regression analysis, with adjustment for age, race, sex, current cigarette smoking, and history of hypertension, diabetes mellitus, atrial fibrillation, and coronary artery disease (defined as previous myocardial infarction, angina, or a coronary artery revascularization procedure). The Breslow-Day Test for Homogeneity was used to evaluate the difference in odds ratios.

### Results

Of the 884 patients tested for aPL antibodies, 467 had aCL testing only, 402 were tested for both aCL antibodies and aPS antibodies, and 15 were tested only for aPS antibodies because of an insufficient amount of sera. In the control group, 1024 individuals were tested for aCL antibodies, and 653 of them (those recruited in the latter part of the study for whom serum samples were stored) were also tested for aPS antibodies.

The demographic and clinical characteristics of patients and control subjects are provided in Table 1. The control subjects were younger, and women represented 54% of the cases and 65% of the control subjects. Most risk factors for stroke, including hypertension, diabetes mellitus, coronary artery disease, and atrial fibrillation were more common in patients. However, we have previously demonstrated that adjusting for these factors does not alter the estimated relative risk associated with a positive aPL antibody titer in our population.13,14

positive aPL titer during the warm weather months. The probability value was <0.001 for this seasonal variation. There was no evidence of a seasonal pattern in the distribution of aPL antibodies in the corresponding patient group. A similar seasonality pattern was noted for each individual aPL isotype among the control subjects (Figure 2, A and B) for whom that aPL result was obtained. Seasonal trends for individual aPL isotypes were not noted among cases (Figure 3, A and B). The probability value for these seasonal trend analyses are given in Table 4.

The odds ratio for any positive aPL titer during the warm weather months (June through September), adjusting for age, sex, race, and traditional stroke risk factors, was 12.3 (95% CI, 6.5 to 23.5). During the other months, the corresponding odds ratio was 2.9 (95% CI, 2.0 to 4.2). This 4-fold difference is statistically significant ($P<0.0003$).

**Discussion**

The presence of aPL antibodies in either primary or systemic lupus erythematosus–related antiphospholipid syndrome is associated with increased risk for thrombosis, but aPL antibodies have been found in up to 14% of normal subjects. Antiphospholipid antibodies have also been detected in malignancies, infections, and drug ingestion; in these conditions, aPL antibodies have not appeared to increase the risk for thrombosis. Drugs that have been reported to induce aPL antibody production include procainamide, phenothiazine, quinidine, and hydralazine. Antiphospholipid antibodies have been detected in sera from individuals with a variety of bacterial and viral infections: mycoplasma, chlamydia, human immunodeficiency virus, Lyme disease, rubella, chicken pox, hepatitis C, and syphilis. Antiphospholipid antibodies in sera from patients infected with Gram-negative bacteria and chlamydia were shown to react to lipopolysaccharide from a rough strain of salmonella. Because phospholipids are constituents of cell membranes, it has been proposed that aPL antibody generation might be an autoimmune response to human tissue damage or a result of cross-reactivity to similar antigens of human tissue and microorganism structures.

Several studies have shown that anionic phospholipids require a cofactor to form a phospholipid-protein complex that presents the antigenic epitope to aPL antibodies. The expression of epitope occurs as the result of the conformational changes of the antigen after the binding of a cofactor to phospholipid. $\beta_2$-glycoprotein I ($\beta_2$GPI), a major cofactor, has been extensively studied. Other proposed cofactors include prothrombin, protein C, protein S, and annexin-V. It has been suggested that aPL antibodies present in autoimmune diseases are thrombogenic and $\beta_2$-GPI–dependent, as opposed to infection-related aPL antibodies, which are thought less likely to be thrombogenic and are $\beta_2$-GPI–independent.

In the present study, the high frequency of aPL antibodies among control subjects occurring in the fall, winter, and
spring is similar to the trends of seasonal respiratory tract infections and resembles the epidemic curve of acute rheumatic fever. Interestingly, there was no evidence of a seasonal distribution of aPL antibodies among the stroke patients. Thus, some of the aPL antibodies of patients and control subjects appear to arise from different origins. Because we have no information regarding previous history or testing for infection in either group, the idea that infection was a contributing factor to aPL antibody production remains speculative. However, if this is the explanation for seasonal variability in antibody positivity in the control group and if aPL antibodies induced by infection are less likely to induce or be associated with a thrombogenetic state, we would expect to see the observed lack of seasonality in the aPL titers of the patient population because any seasonal variation would be obscured by the high proportion of antibodies unrelated to infection. We do not exclude the possibility that even thrombogenic aPL antibodies might arise in response to infection through a “molecular mimicry” mechanism analogous to acute rheumatic fever. Further studies on the prevalence of other autoantibodies, which would elucidate this point, are planned.

Our results suggest that in an apparently normal population, there is seasonal variability in aPL antibody titers. This could arise from certain seasonal infections, but this remains to be proven. The nonthrombogenicity of aPL antibodies related to infection and drug induction has not yet been established, but our data suggest that the apparent relative risk for stroke associated with aPL antibodies may be considerably higher in the summer months and conversely lower at
other times. If this seasonal variability is confirmed in other cohorts, it may be necessary to consider the implications for subsequent study design. It may also help to explain the apparent discrepancies in previous studies. If, for example, subjects were recruited exclusively during cold weather months, the prevalence in unselected (nonstroke) populations would tend to appear higher, but the association with stroke (and possibly other vascular events) would appear weaker, whereas a prospective cohort recruited primarily in warm weather months may demonstrate a lower prevalence of elevated aPL titers but stronger relation of those titers to stroke.
