Cerebral Blood Flow Restoration and Reperfusion Injury After Ultraviolet Laser–Facilitated Middle Cerebral Artery Recanalization in Rat Thrombotic Stroke

Brant D. Watson, PhD; Ricardo Prado, MD; Alexander Veloso, BS; J-P. Brunschwig, BS; W. Dalton Dietrich, PhD

Background and Purpose—A reversible model of focal thrombotic stroke was developed in the rat and examined for histological evidence of reperfusion injury after clinically relevant times of recanalization.

Methods—The distal middle cerebral artery of 28 male Sprague-Dawley rats was occluded by 562-nm laser-driven photothrombosis for 0.5, 2, and 3 hours or permanently (each n=7) and was recanalized by 355-nm UV laser irradiation. Occlusive material was examined by transmission electron microscopy. Cortical cerebral blood flow was monitored by laser-Doppler flowmetry. Brain infarcts were examined histologically at 3 days.

Results—After occlusion, cortical cerebral blood flow was reduced to 33±4% of baseline for all groups and was restored to 82±9%, 75±3%, and 93±7% of baseline for the 0.5-, 2-, and 3-hour groups, respectively, following recanalization after 29±8, 38±20, and 70±33 minutes of UV laser irradiation. The thrombotic occlusion contained compactly aggregated platelets but no fibrin, with length (1.2 to 1.8 mm) proportional to the ischemic period. During recanalization, microchannels containing erythrocytes and scattered leukocytes and bordered by intact disaggregated platelets infiltrated the thrombus. Infarct volumes (mm3) at 3 days were 12±4, 24±3, and 30±9 for the 0.5-, 2-, and 3-hour cases, respectively, thus demonstrating reperfusion injury histologically in the latter 2 groups. No hemorrhage was seen.

Conclusions—UV laser–facilitated dissolution of a conventionally refractory platelet thrombus provides a novel and effective method for restoring blood flow without hemorrhagic complications during thrombotic stroke. This was the first observation of histologically confirmed reperfusion injury in such a model. (Stroke. 2002;33:428-434.)

Key Words: laser  platelet aggregation  reperfusion injury  stroke, ischemic  thrombolysis  rats

A nimal models of thrombotic or thromboembolic stroke are becoming increasingly important in basic and preclinical studies of prospective therapies, especially those concerned with thrombolytic1 and, more recently, antiplatelet regimens.2 Occlusive platelet thrombi are of particular concern because they contain little or no fibrin3 and thus are extremely resistant to thrombolytic drugs such as the tissue plasminogen activators approved for acute stroke therapy.3–7 The prevention or removal of refractory platelet thrombi has attracted much interest, as shown by the increasing utilization of arginine-glycine-aspartic acid antagonists2,3,8–10 and thrombin inhibitors11 to inhibit or destabilize intraplatelet fibrinogen cross-links between platelet glycoprotein (GP) IIb-IIIa membrane receptors. Experimentally, such a fibrin-free white thrombus can be produced photochemically in arteries in vivo by a process termed laser-driven photothrombosis.12 Although we often have used this technique to occlude the distal middle cerebral artery (MCA) to simulate thrombotic stroke in the rat,13–15 studies of the consequences of reperfusion after clot lysis in these models have been very few, requiring special conditions. For example, “soft” platelet thrombi transiently occluding an MCA segment can be dissolved hemodynamically after local vasodilation with nimodipine.16

A search for a more focal method of vasodilation revealed that UV light exposure from a filtered arc lamp could relax preconstricted aortic rings prepared in vitro17 and also arteries in vivo by irradiation with pulsed 351-nm XeF18 or 248-nm Krf19 UV lasers. The mechanisms of dilation are attributed to photoacoustic alteration of smooth muscle contractile proteins by shock waves generated during erythrocyte vaporization at high laser-energy density20 or photolytic release of nitric oxide at low energy density,19 respectively. Accordingly, we examined the capability of a 355-nm pulsed, low energy-density UV laser to dilate the patent rat MCA and then to dilate and recanalize the occluded MCA after photo-
thrombosis, concurrent with laser-Doppler measurements of
cortical cerebral blood flow (CBF). Full recanalization was
complicated by extensive deposits of occlusive material
(examined by transmission electron microscopy [TEM]) ad-
jaent to the primary platelet thrombus. Finally, we examined the
distal MCA territory 3 days afterward for histological
evidence of cerebral reperfusion injury.

Materials and Methods

Surgical Preparation

All animal surgical and maintenance procedures were approved by the
Animal Care and Use Committee of the University of Miami in
accordance with US Public Health Service regulations. Briefly, male
Sprague-Dawley rats (n=34) weighing 250 to 350 g were anesthe-
tized with 2.5% halothane in a 70%/30% mixture of nitrous oxide
and oxygen and were maintained on 1% halothane by means of
mechanical ventilation. The left distal MCA was exposed via a 3-mm
burr hole with the dura intact, essentially as previously de-
scribed,13,14 with head and body temperatures maintained at 36
°C. A second burr hole was created between the coronal and
sinus, and images of the vascular field were obtained with a
Zeiss), and images of the vascular field were obtained with a

4.5-ns pulses at a rate of 20 Hz and a UV wavelength of 355 nm was
used to irradiate the distal MCA. Laser power was measured with a
detector head (model 380101) interfaced to a power meter (model
365, Scientech). The UV laser beam was spatially and optically
filtered, expanded by a ×10 beam telescope (model BXUV-4.0-10X,
CVI Laser Corp) and then focused by a 25-cm focal length BK7
glass plano-convex lens onto the distal MCA, encompassing its
diameter. Diameter of the patent distal MCA with the UV laser beam
was examined quantitatively in a closed cranial (fused silica)
window preparation (n=7).13

Recanalization of an occluded distal MCA was begun by low-

intensity UV laser irradiation (approximately 20 mW/mm²) imme-
diately proximal to the occlusion. This induced dilation of the
adjacent thrombosed segment, and thin rivulets of fresh blood were
observed to infiltrate the thrombus rapidly. The UV intensity was
then increased until the infiltrating blood columns coalesced, indi-
cating disappearance of thrombosed material and recanalization of
the segment. The UV beam was then advanced distally (by approxi-
mately half the segment diameter), and the process was repeated
until complete recanalization was observed visually and verified by
normalization of cortical CBF. The duration of irradiation and laser
power were then recorded. The primary thrombus segment was the
most vasoconstricted and thus required more UV intensity and time.
Exposure of dural vessels to UV irradiation was minimized to avoid
hemorrhage.

Light Microscopic Analysis of Infarct Volume

Animals that underwent distal MCA occlusion were perfusion-fixed at
3 days in FAM (40% formaldehyde, glacial acetic acid, and
methanol, 1:1:9 by volume), and their brains were embedded in
apparafin from which 10-μm-thick sections were obtained at 25-μm
intervals and stained by hematoxylin and eosin, as described previ-
ously.14 For calculating infarct volume, histological sections at 8
 coronal levels were digitized at ×1 power by means of a CCD
camera (Xillix Technologies Corp), or microscopic images were
digitized by means of a Sony CCD color video camera, and data
were recorded with an MCID image analysis system (Imaging
Research, Inc). Total infarct volume was derived by numerical
integration of sequential infarct areas according to Simpson’s rule,
with correction for edema.22 Areas bordering the infarct epicenter
were evaluated for incomplete infarction (a mixture of normal and
necrotic neurons)13 at ×400 magnification.

TEM Analysis

Animals were transcardially perfused beginning with a 2-minute
flush of isotonic saline delivered at a pressure equal to the rat’s mean
arterial blood pressure, followed by 500 mL of fixative solution
composed of 2% glutaraldehyde and 100 mmol/L sucrose in 0.05
mol/L NaPO₄ buffer. The brain was removed and placed overnight
in fresh fixative chilled to 4°C. The desired distal MCA segment was
carefully removed from the surface of the brain, placed into a 1% solution of OsO₄ in 0.1 mol/L NaPO₄ buffer, and stored overnight at
4°C. The segment was then prepared for TEM essentially as

described previously and was examined and photographed in a TEM (model CM-10, Philips Research Laboratories) operated at 60 or 80 kV.

Statistical Analysis

Differences in infarct volume and CBF among the treatment groups were determined by ANOVA followed by Newman-Keuls test. All data are expressed as mean ± SD.

Results

Physiological Variables

Physiological variables are shown in Table 1. No significant changes were observed throughout the experiment.

Response of the Patent Distal MCA to UV Laser Irradiation

In the closed cranial window preparation, the patent distal MCA in the initial group of 7 rats was exposed for 2 minutes to 355-nm pulsed UV laser irradiation; a typical response over time is shown in Figure 1. Dilations with respect to baseline of 64%, 18%, and 24% were observed after 5 seconds, 1 minute, and 2 minutes, respectively, and essentially unchanged for 30 minutes afterward.

Response of the Occluded Distal MCA to 355-nm UV Laser Irradiation

Recanalization of occluded segments aged for 0.5 to 3 hours was facilitated by 355-nm UV laser irradiation as described in Materials and Methods and was observed in every treated rat. Figure 3 depicts UV treatment of a thrombotic occlusion aged for 3 hours. The original diameter of the entire segment was recovered, but some mural thrombotic material appeared intermittently up to 2 hours after UV treatment. The average UV beam intensity at the onset of recanalization was 48 ± 32 mW/mm² (n=21). The irradiation time required for recanalization was proportionate to the age of the thrombus (r=0.96, P<0.001; Table 2).

Figure 1. Representative response of the distal MCA in a naive rat to 2 minutes of 355-nm pulsed UV laser irradiation at a rate of 20 Hz and an average intensity of 50 mW/mm². A, B, C, D (B to D scale same as A), Diameter responses at baseline (196 μm), 5 seconds (214 μm), 1 minute (230 μm), and 2 to 30 minutes (238 μm), respectively, after start of irradiation. Note proximal and distal migration of the dilation effect.

Figure 2. Response of distal MCA to rose bengal–mediated photothrombotic occlusion initiated by 562-nm dye laser irradiation. A, Position of irradiating beam before irradiation. B, Primary thrombus 30 minutes after its formation with beam position designated with arcs (scale same as A). C, Light microscopic view of distal MCA segment perfusion-fixed at 30 minutes, containing primary thrombus (braces) with proximal and distal extensions. Note distal erythrocyte cap (arrow). D, TEM view of proximal end occlusion. Note predominant platelet composition and erythrocyte infiltration along arterial wall. Magnification ×2400. E, TEM view of distal end, showing sharply delineated border between the mass of aggregated platelets and the end cap composed of clumped erythrocytes. No fibrin is detected. Magnification ×1620.
The process of recanalization was examined structurally in another distal MCA segment after an occlusive thrombus was aged for 0.5 hour (Figure 4A) and then underwent UV treatment until blood appeared to infiltrate its proximal half (Figure 4B) and surrounded the thrombus concomitant with distal MCA dilation (Figure 4C). More interesting, however, was the penetration of blood directly into the thrombus owing to the formation of multiple internal channels congruent with and even beyond the UV beam location (Figure 4C). Under TEM, the borders of the proximal infiltrating channels are composed of platelets that appear to have separated cleanly from their cross-channel neighbors (Figures 5A and 5C). In distal channels, however, the borders may be diffuse owing to mechanical damage to platelet membranes (Figure 5B). The channels thus comprise a complicated network filled with erythrocytes, plasma, and occasional leukocytes. No degradation of the infiltrated erythrocytes under 355-nm UV irradiation was seen, thus indicating the absence of destructive photoacoustic effects, but vacuolation that had developed in smooth muscle cells in the primary photothermolysed segment was exacerbated (not shown). No vacuolation was seen in UV laser–irradiated patent segments.

Response of Cortical CBF to Occlusion and Subsequent Recanalization

The time histories of cortical CBF response to the permanent occlusion experiment and to the experiments based on occlusion for 0.5, 2, and 3 hours followed by recanalization are shown in Figure 6. Laser-Doppler cortical CBF was reduced to 30±3% of baseline for permanent occlusion and 36±4%, 37±2%, and 35±2% of baseline for the 0.5-, 2-, and 3-hour groups, respectively. The ischemic periods were followed by time intervals representing the average times for UV treatment for each group (Table 2) until resumption of cortical CBF to near-normal levels, amounting to 82±9%, 75±3%, and 93±7% of baseline for the 0.5-, 2-, and 3-hour groups, respectively, during 2 hours of observation after full recanalization.

Reperfusion Injury in the Distal MCA Territory

Brain infarcts in the 4 groups at 3 days appeared only in the ipsilateral hemisphere, were confined to the dorsolateral cerebral cortex, and displayed typical cellular alterations consistent with ischemic necrosis. Infarct volumes were 12±3 mm$^3$ for the permanent cases and 8±4, 24±3, and 30±9 mm$^3$ for the cases in which recanalization was begun after 0.5, 2, and 3 hours of thrombosis-induced ischemia (Figure 7). Because the infarct volumes for the 2- and 3-hour

cases far exceeded that for the permanently occluded cases ($P<0.001$), reperfusion injury is thus demonstrated. No hemorrhages were observed. In addition, incomplete infarction was observed sporadically at the periphery of the infarct epicenter as a small percentage of its area. For the permanent, 0.5-, 2-, and 3-hour groups, this was 4.3%, 0.45%, 4.0%, and 1.5%, respectively. The frequency of occurrence in each group was 5 of 7, 1 of 7, 4 of 7, and 3 of 7, respectively.

**Discussion**

These studies have revealed that (1) a cerebral artery occluded by an extensive, fibrin-free platelet thrombus can be recanalized by a novel laser method that instigates the formation of multiple, progressively enlarging channels in the thrombus interior and (2) CBF can be restored to nearly normal levels at clinically relevant times, only to engender reperfusion injury. This occlusive platelet thrombus is intracatable to conventional lytic methods, but the UV laser method overcomes these limitations and thus provides an unusual and effective means to restore blood flow during thrombotic stroke. Direct UV irradiation of the stabilized platelet mass is evidently unnecessary, because the intrathrombus channels can still form distal to that point (Figure 4C). It may also be possible to recanalize cerebral arterial branches indirectly owing to the diffusible nature of the dilation effect (Figure 1). Finally, because cerebral ischemia in this model is induced by occlusive thrombosis only, collateral pathways are not compromised by concurrent mechanical ligature (eg, of the common carotid arteries) and are thus available as pharmacological conduits. This model of reversible thrombotic stroke is therefore reduced to its most essential aspects.

There is no established mechanism to explain how UV laser–induced dilation facilitates formation of the microscopic intrathrombus channels that lead to recanalization of a platelet-occluded artery (Figure 4C). This process nonetheless engenders a decrease in thrombus density and thus provides pathways for blood permeation along with enhancement of surface area available for plasma protein or exogenous drug interaction at enhanced efficacy. To illustrate, during channel formation the platelets appear to separate cleanly (Figure 5A and 5C) as if by dethrombosis. Treatment with an antibody to the platelet GPIb-IIIa receptor alone was correlated with channel formation in coronary thrombi in dogs and establishment of reflow in dogs and in humans as well, possibly owing to enlargement of preexisting seepage channels. Arterial flow pulsations may further erode the integrity of interplatelet binding. Mechanical and ultrasonic means have also been used to destabilize a thrombus to enhance the potency of thrombolytic agents (eg, recombinant tissue plasminogen activator). Alternatively, local intra-arterial infusion of urokinase achieved acceptable recanalization of the MCA trunk in up to 66% of clinical cases after 2 hours of treatment, although the frequency of symptomatic intracranial hemorrhages was observed. In addition, incomplete infarction was observed sporadically at the periphery of the infarct epicenter as a small percentage of its area. For the permanent, 0.5-, 2-, and 3-hour groups, this was 4.3%, 0.45%, 4.0%, and 1.5%, respectively. The frequency of occurrence in each group was 5 of 7, 1 of 7, 4 of 7, and 3 of 7, respectively.

**Figure 4.** Open cranial view of an occlusive thrombus aged for 0.5 hour (A, primary thrombus site designated by arcs) and then treated for 17 minutes with 355-nm UV laser irradiation until the primary thrombus was infiltrated with blood along half its length (B scale same as A). C, Light microscopic appearance of partially recanalized segment depicting the thrombus surrounded and penetrated by multiple channels containing infiltrated blood (arrowheads). PT designates location of primary thrombus; UVT, final position of UV treatment beam. Blood infiltration at an early stage is also developing distal to the UVT position (arrowheads). P denotes regions of compactly aggregated platelets.

**Figure 5.** TEM analysis of recanalization in the thrombus of Figure 4C at an adjacent transverse plane. A, At the proximal end, the interior channel borders are composed mostly of disengaged platelets with intact pseudopodia (large arrows), but more distally, some platelet membranes appear indistinct (asterisk) in a region of highly compacted platelets. Many erythrocytes are seen, along with some leukocytes (small arrows). Magnification $\times1400$. B, View of another distal channel showing partial or complete disappearance of platelet membranes (arrows) and exposure of their cytoplasm. Magnification $\times7600$. C, View of channel at lower right in A. More commonly, platelets have disengaged from their cross-channel neighbors by cleanly unraveling their pseudopodia (arrows). Magnification $\times3150$. 
rhage was 10%. Recently, a percutaneously transmitted high
energy-density dye laser beam has been used clinically to
disintegrate brain artery occlusions photoacoustically. With
similar optical fiber technology, percutaneous UV laser
irradiation at much lower energy densities may possibly
augment or substitute for intra-arterial thrombolytic interven-
tions. Finally, although platelet arginine-glycine-aspartic
acid inhibitors have augmented thrombolytic therapy clini-
cally and have suppressed platelet accumulation in ischemic
microvessels in baboons, they cannot be used in the rat
because a conformational change in the rat platelet GPIIb-IIIa
receptor after binding of the inhibitor drug allows fibrinogen
to bind as well. The UV laser method nonetheless facilitates
the dissociation of intraplatelet binding forces, with appar-
ently endogenous factors or their derivatives that are
insensitive to this limitation.

However, despite near-complete restoration of cortical
CBF in the reversible thrombotic stroke groups, histological
infarct volumes at 3 days after reperfusion at the relatively
late absolute times of 3 to 4 hours were enhanced by 2- to
2.5-fold compared with the permanently occluded group. The
chief criterion for reperfusion injury, ie, conversion of tissue
from a reversible to an irreversible state of injury, is thus
fulfilled. Such direct evidence for reperfusion injury in
thrombotic stroke has not been reported previously. Possible
potentiators of thrombotic reperfusion injury include platelet
secretions that evidently damage the blood-brain barrier
downstream and presage severe morphological changes in
neurons, astrocytes, and endothelium. The participation of
acute inflammation is indicated by the intense platelet aggre-
gation distal to the primary thrombus, which likely elicits a
similar response in the ischemic microvasculature and also
by the acute association of leukocytes with the recanalizing
thrombus (Figure 5A). Previously, reperfusion injury was
demonstrated in the brains of rats mechanically recirculated
between 2 and 5 hours after dual-ligature occlusion (MCA
and ipsilateral common carotid artery) as approximately
3-fold enhancement of infarct volume at 1 day compared with
the permanently occluded group. Our cortical CBF results
(Figure 5) indicate that reperfusion injury is potentiated by
intermediate, but not severe, levels of ischemia in cerebral
tissue and by delayed cortical CBF restoration and blood-
brain barrier damage. Identification of the processes
contributing to reperfusion injury in our reversible model of
thrombotic stroke now appears feasible, as does study of their
eventual mitigation.
Acknowledgments

This work was supported by US Public Health Service grants RO1 NS23244 (Dr. Watson) and RO1 NS27127 (Dr. Dietrich) from the National Institute of Neurological Disorders and Stroke. The authors thank Rob Camarena for photography, the electron microscopy core of the Miami Project to Cure Paralysis for tissue analysis, Guillermo Hernandez for histology, David Smith and Weizhao Zhao for image processing, Professor F.W. Flitney for discussions on vasodilation, and Dr Per Wester for critical reading of the manuscript and specific suggestions for improvement. Technical information concerning UV laser–facilitated dissolution of platelet occlusions was included in a US patent application filed June 11, 2000, to preserve the possibility of its extension to clinical use.
