Cerebral Perfusion and Cerebrovascular Reactivity Are Reduced in White Matter Hyperintensities

J.R. Marstrand, MD; E. Garde, MD, PhD; E. Rostrup, MD, MSc; P. Ring, MSc; S. Rosenbaum, MD, PhD; E.L. Mortensen, PhD; H.B.W. Larsson, MD, PhD

Background and Purpose—There is growing evidence that white matter hyperintensities (WMH) should not be considered as benign age-dependent changes on MR images but indicate pathological changes with clinical consequences. Previous studies comparing subjects with WMH to normal controls have reported global reductions in cerebral blood flow (CBF) and cerebral vascular reactivity. In this study, we examined localized hemodynamic status to compare WMH to normal appearing white matter (NAWM).

Methods—A group of 21 normal 85-year-old subjects were studied using dynamic contrast-enhanced MRI together with administration of acetazolamide. From a combination of anatomic images with different signal weighting, regions of interest were generated corresponding to gray and white matter and WMH. Localized measurements of CBF and cerebral blood volume (CBV) and mean transit time were obtained directly within WMH and NAWM.

Results—When comparing WMH to NAWM, measurements showed significantly lower CBF ($P < 0.004$) and longer mean transit time ($P < 0.001$) in WMH but no significant difference in CBV ($P = 0.846$). The increases in CBF and CBV induced by acetazolamide were significantly smaller in WMH than in NAWM ($P = 0.026, P < 0.001$).

Conclusion—These results show that a change in the hemodynamic status is present within the WMH, making these areas more likely to be exposed to transient ischemia inducing myelin rarefaction. In the future, MRI may be used to examine the effect of therapeutic strategies designed to prevent or normalize vascular changes. (Stroke. 2002;33:972-976.)

Key Words: hemodynamics ■ magnetic resonance imaging, perfusion-weighted ■ white matter

There is increasing evidence of an association between white matter hyperintensities (WMH), also described as leukoariosis,1 and reduction in different cerebral functions, supporting the view that the presence of WMH represents pathological changes. WMH are related to impaired lower extremity function2 and to both subjective and objective cognitive failure.3,4 and are also associated with an age-related decline in cognitive functions.5 Changes in white matter tracts measured by diffusion-weighted MRI have been associated with degree of cognitive function.6 WMH are known to be highly related to age7,2 but are also independently related to risk factors for cardiac and cerebral vascular disease.5–10 It is, however, unclear to what extent white matter changes are caused by pathology in the cerebral vessels. Myelin rarefaction and changes in the small penetrating arteries have been described in conjunction with changes in WMH,11,12 suggesting that ischemia contributes to lesion formation.4 In support of this hypothesis, different techniques have shown that reduced cerebral blood flow (CBF)13,14 and cerebrovascular response to acetazolamide (ACZ) or CO₂ are both related to the degree of white matter changes.15–17 These studies, however, did not examine specifically the CBF or the cerebrovascular reactivity (CVR) within the WMH but measured global CBF or CVR and compared results from subjects with WMH to normal control subjects.

The purpose of this study was to examine the hemodynamics within WMH and compare it to the normal appearing white matter (NAWM) in a group of 85-year old individuals from the Glostrup Population Studies.18 Hence, perfusion and CVR measurements within WMH, gray matter, and NAWM were performed using a combination of MR perfusion imaging and conventional anatomic MR imaging.

Methods

Subjects
Since 1964, a cohort of people born in 1914 and living in municipalities close to Copenhagen County General Hospital and the County Mental Hospital in Glostrup has participated in follow-up studies of their medical, social, and mental health status. Studies have been conducted in 1964, 1974, 1984, 1989, 1995, and 2000. In 2000, the study included physical and psychological examinations performed in the home of the participants. All 121 participants undergoing psychological examination were asked if they would...
consider participating in the MR examination. Forty-seven persons consented to be contacted for further information; of these, 22 agreed to participate. One subject could not be examined because of a body posture incompatible with the head coil. The 21 subjects examined (13 men, 8 women) had a mean age of 85.8 (range, 85 to 86) years at the time of the MR examination. Sixteen subjects (9 men, 7 women) underwent the full MR protocol, whereas the remaining 5 did not receive ACZ either because of contraindications (2 subjects) or because they were unwilling to go through the entire examination (3 subjects). The study was approved by the local Scientific-Ethical Committee of Copenhagen County (KA 99167).

Imaging Procedure

Imaging was performed using a 1.5 T MR scanner (Vision, Siemens Erlangen) utilizing a circularly polarized head coil. The imaging protocol consisted of a T1-weighted MPRAGE (TR/TE=11.4/4.4 ms, TI=100 ms, FA=8°, FOV=250 mm, matrix=224×256) with 1-mm isotropic voxels covering the entire head; a proton and T2-weighted double spin-echo (DSE) sequence (TR/TE=2880/20 and 80 ms, FA=90°, FOV=230 mm, matrix=256×256) with 60 slices of 2 mm measured interleaved using 2 separate acquisitions; and a T2-weighted FLAIR sequence (TR/TE=9000/110 ms, TI=2500 ms, FA=180°, FOV=230 mm, matrix=220×512) with 30 slices of 5 mm measured interleaved using 2 separate acquisitions. Perfusion-weighted MRI was performed as a dynamic susceptibility contrast (DSC-MRI) study using a T1*-sensitive gradient echo–echo planar imaging (GE-EPI) sequence (TR/TE=1000/66 ms, FA=60°, FOV=250 mm, matrix=128×128, 6 slices, 5 mm, 12 measurements). During the GE-EPI sequence, Gd-DTPA (Magnevist, Schering) was injected in an antecubital vein, using an MR-compatible double-syringe power injector (Spectris MR Injector, Medrad Inc.). The Gd-DTPA (0.1 mmol/kg) injection was started at the 15th measurement with an injection rate of 3 mL/s, followed by 20 mL saline at 3 mL/s. Two DSC-MRI studies were performed before and after administering 1 g of ACZ (Diamox, Wyeth Lederle) injected manually over a period of 5 minutes. The second DSC-MRI study was performed at an average time of 19 (range, 16 to 27) minutes after ACZ injection. All images were axial, and the DSE, FLAIR, and DSC images were obtained in a plane parallel to the line through the anterior and the posterior commissure.

Image Analysis

All image data were transferred to a Linux-based PC system for post-processing. All images including the DSC-MR images were coregistered to the FLAIR image (DSE in 3 cases) using a rigid-body registration (Figure 1). The registration algorithm is based on the principle of maximal mutual information in the combined histogram of the 2 images being registered.20,21 Parametric maps representing CBF, cerebral blood volume (CBV), and mean transit time (MTT) were calculated from the DSC-MR images using a method described previously.21 In short, the images were converted into ΔR2 maps by use of the relation in Equation 1,

\[ C_{voi}(t) = \Delta R_2(t) = \frac{1}{TE} \ln \left( \frac{S_a(t)}{S_0} \right) \]

where ΔR2 is proportional to the concentration of contrast agent with the proportionality constant \( \kappa_{voi} \) also known as the relaxivity. \( S_a(t) \) is the voxel signal at time \( t \), \( S_0 \) is the baseline voxel signal before contrast arrival, and \( TE \) is the echo time. From the converted images, a voxel representing an arterial input curve was selected from voxels having maximal amplitude and short arrival time. CBF was set to the peak point of the solution to Equation 2,

\[ C(t) = CBF \cdot C_a(t) \cdot (1 - H(t)) \]

where \( C \) is the tissue concentration, \( C_a \) is the concentration in the feeding artery, and \( 1 - H(t) \) is the residue impulse response function. This solution was found by the singular value decomposition (SVD) method described by Østergaard et al.,22 as well as by a least square fitting algorithm, fitting an exponential function as the residue impulse response function. CBF and MTT were then calculated from Equations 3 and 4, respectively.25

\[ CBV = \frac{C(t) \cdot \int_0^\infty (1 - H(t)) \, dt}{CBF} \]

\[ MTT = \frac{CBV}{CBF}. \]

In our previous work,21 GE-EPI DSC-MR studies on healthy volunteers with sequence acquisition parameters equal to this study gave absolute CBF and CBV values 6.5 times higher than positron emission tomography values in the literature,24 because of underestimation of the arterial input function. Consequently CBF and CBV values are therefore scaled by a factor of 1/6.5 in this study. The parametric maps were spatially transformed onto the FLAIR images, and the 6 anatomic slices corresponding to the perfusion maps were selected for semiautomated region of interest (ROI) generation. This was performed by drawing reference regions in white matter, gray matter, cerebrospinal fluid, and WMH in all 6 slices. Pixels with signal intensities within ±2 SD from the median signal intensity in the reference region on all anatomic image modalities were included in the corresponding ROI. ROIs with volume less than 40 mL for white and gray matter, 2 mL for cerebrospinal fluid, and 0.5 mL for WMH were excluded. To minimize partial volume effects, any voxel falling into more than 1 tissue type ROI was also excluded. By only generating regions in the 6 slices, no signal intensity changes due to field variation along the main magnetic field were present. This procedure resulted in region volumes of 102±26 mL for gray matter, 92±22 mL for white matter, and 7±6 mL for WMH (see Figure). The generated ROI sets were visually inspected, and voxels included as WMH situated outside the area of white matter (eg, plexus choroideus) were excluded. The resliced parametric maps measured before ACZ were subtracted from the maps measured after ACZ to create difference maps. Mean CBF, CBV, and MTT values before

Registered anatomic images (FLAIR, MPR, PD, T2W), parametric maps (CBF, CBV, MTT), and region of interest (ROI) map. The ROI set contains gray matter, white matter, and white matter hyperintensity ROIs. Flair indicates FLAIR; MPR, MPRAGE; PD, proton density; T2W, T2-weighted; CBF, cerebral blood flow; CBV, cerebral blood volume; MTT, mean transit time.

CBF, CBV, MTT, and difference values are calculated on a pixel basis before obtaining the mean regional values. ACZ indicates acetazolamide; ROI, region of interest; CBF, cerebral blood flow; CBV, cerebral blood volume; MTT, mean transit time; GM, grey matter; NAWM, normal appearing white matter; WMH, white matter hyperintensities.

and after ACZ, as well as the difference for each parameter were calculated for each ROI.

Discussion

This study has demonstrated that both CBF and CVR are reduced and MTT is increased in areas with WMH as compared with NAWM. Although several previous reports support our findings of altered hemodynamics in relation to WMH, to our knowledge this is the first study demonstrating this by using high-resolution perfusion-weighted MR. Previous studies have not measured the hemodynamic status specifically within the WMH and compared it to surrounding NAWM, but have compared CBF in global white matter in individuals with WMH to individuals without WMH. Reduced CBF in global white matter associated with WMH has been shown by positron emission tomography, single-photon emission computed tomography, and Xe-CT. In addition, using transcranial Doppler sonography (TCD), Tzourio et al found the degree of WMH to be associated with a reduction in MCA blood flow velocity. Because of the absence of a control group, it cannot be excluded that CBF in NAWM is itself reduced in our study population compared with CBF in NAWM in subjects without WMH. Hatazawa et al found a global white matter CBF reduction of 14%, whereas the reduction in CBF between WMH and NAWM in this study was 29%, suggesting that the measured reduction in global white matter CBF reflects local changes in WMH. Our finding of a reduced CVR within WMH is in accord with previous findings. Oishi and Mochizuki, using Xe-CT, found a significantly reduced CVR in patients with leukoariosis compared with controls. Isaka et al measured cortical CVR using a surface detector system and Xe clearance and found a significant negative correlation between CVR and the severity of periventricular hyperintensities. Reduction in CVR measured by CO2-enhanced TCD has also been associated with the extent of WMH. However, Ture et al were unable to find any significant reduction in CVR in the white matter of subjects with leukoariosis compared with normals. As pointed out by that group, the limited resolution in their CBF images with subsequent partial volume effects between tissue compartments could explain why no differences were detected.

Our results are a strong indication of an altered hemodynamic status within the WMH compared with the surrounding tissue and of WMH representing a pathological vascular state. Several histological studies report vascular changes in relation to WMH as well as varying degrees of ischemic injury. It would be expected that reduction in CBF...
would render the tissue more sensitive to alterations in perfusion pressure, and it is noted that WMH have been associated with orthostatic hypotension. The association between hypertension and WMH supports the theory of vessel disease causing these lesions. Sander et al. found a relationship between elevated nighttime systolic blood pressure and WMH, whereas Schmidt et al. found that the LL PON1 genotype, which has been associated with small-vessel disease retinopathy, influenced the progression of WMH. The altered hemodynamics due to induced vessel changes could cause rarefaction of the myelin sheaths as consistently found in histological studies of WMH.

Our results were obtained in a selected group of 85-year-old subjects with an expected high prevalence of WMH. Whether other age groups exhibit the same hemodynamic changes in WMH as found in this study needs to be established.

Regional differences in vasculature and histopathological changes suggest a distinction between deep and periventricular WMH. Our ROI-generating program selected regions with regard to signal intensities, and not anatomical location, on the basis of manually drawn reference regions, and by combining the information from several images with different signal weighting. Partial volume effects were reduced by excluding voxels selected for more than 1 tissue, thereby obtaining ROIs specific to the different tissue types. The WMH ROIs could potentially have been stratified based on their location in deep and periventricular regions, but our data set was not large enough for such a stratification. To perform this stratification in a greater population as well as combining the hemodynamic information with information from MR diffusion and spectroscopic measurements would be of interest and is the aim of future studies.

In the group of 85-year-old volunteers, ACZ induced a significant increase in both CBF and CBV, smaller than the increase measured in our previous study of a group of normal elderly. Furthermore, we suggest that this approach could be a step toward examining the effect of therapies designed to prevent or normalize vascular changes.

### Conclusion

We have shown for the first time that perfusion and CVR are reduced within WMH in comparison to the NAWM in a group of normal elderly. Furthermore, we suggest that this approach could be a step toward examining the effect of therapies designed to prevent or normalize vascular changes.
