Association Between Carotid Artery Plaque Ulceration and Plaque Composition Evaluated With Multidetector CT Angiography

Philip J. Homburg, MD*; Sietske Rozie, MD*; Marjon J. van Gils, MD; Quirijn J.A. van den Bouwhuijsen, MD; Wiro J. Niessen, PhD; Diederik W.J. Dippel, MD, PhD; Aad van der Lugt, MD, PhD

Background and Purpose—Symptomatic carotid artery plaque ulceration is associated with distinct plaque components such as a large lipid-rich necrotic core (LR-NC) in ischemic stroke patients with a ≥50% carotid stenosis. We evaluated the associations between carotid artery plaque ulceration and plaque characteristics in ischemic stroke patients with ≥50% stenosis, as well as in those with a low degree of stenosis (0% to 49%).

Methods—Consecutive patients (n=346) with symptoms in the anterior circulation were evaluated with multidetector CT angiography (MDCTA) for the presence of atherosclerotic plaque, degree of stenosis, and plaque ulceration in the symptomatic carotid artery. Plaque volume and plaque component proportions of LR-NC, fibrous tissue, and calcification were measured. The associations between plaque ulceration and plaque characteristics were analyzed using logistic regression.

Results—Atherosclerotic plaque was present in 185 patients. Plaque ulcerations were present in 38 (21%) patients, of which half had a low degree stenosis (0% to 49%). Plaque volume was significantly larger in ulcerated plaques. After adjustment for age, sex, and degree of stenosis, LR-NC proportion was strongly associated with plaque ulceration (odds ratio, 2.21; 95% CI, 1.49 to 3.27), whereas calcification proportion was inversely associated with plaque ulceration (odds ratio, 0.60; 95% CI, 0.40 to 0.89). These associations remained significant in patients with a low degree stenosis (0% to 49%).

Conclusion—Plaque volume, degree of stenosis, and LR-NC proportion evaluated noninvasively with MDCTA are associated with carotid artery plaque ulceration, even in patients with a low degree stenosis (0% to 49%). Plaque volume and composition analysis with MDCTA may identify rupture prone plaques and improve risk stratification in ischemic stroke patients. (Stroke. 2011;42:367-372.)

Key Words: atherosclerosis ■ atherosclerotic plaque composition ■ carotid artery ■ CT ■ ulceration
tics with plaque ulceration in symptomatic carotid arteries with significant stenosis (≥50%), as well as in those with a low degree stenosis (0% to 49%).

Methods

Study Population
From a prospective registry of 911 consenting patients with amaurosis fugax, transient ischemic attack, or ischemic stroke (Rankin score, <4) who underwent MDCTA of the carotid arteries, we selected a 2-year cohort of consecutive patients (n=346) with symptoms in the anterior circulation. Patients were enrolled from a specialized transient ischemic attack/stroke outpatient clinic or the neurology ward. All patients underwent an interview, neurological examination, electrocardiography, laboratory analysis, and MDCTA on admission. Medical history and cardiovascular risk factors, as defined previously,7 were recorded. Patients without atherosclerotic plaque (n=137), with carotid occlusion (n=20), and with an MDCTA of insufficient quality (n=4) were excluded from the analysis.

MDCTA Data Acquisition and Data Analysis
Imaging was performed with a 16-slice MDCT scanner (Sensation 16, Siemens, Erlangen, Germany) or a 64-slice MDCT scanner (Sensation 64, Siemens, Erlangen, Germany) with a standardized optimized contrast-enhanced protocol (120 kVp, 180 mAs, collimation 16×0.75 mm or 64×0.6 mm, pitch ≤1). Details of the MDCTA scan protocol have been described previously.7,9

MDCTA images were sent to a stand-alone workstation (Leonardo, Siemens Medical Solutions, Forchheim, Germany) with dedicated 3D analysis software. The symptomatic carotid bifurcation was evaluated by 2 experienced investigators blinded to clinical data with multiplanar reformattting software, which allows reconstruction of sagittal, coronal, and oblique views from axial sections. Discrepancies were solved by consensus.

Symptomatic carotid arteries were evaluated for the presence of atherosclerotic plaque, defined as thickening of the vessel wall or the presence of calcification. Plaque ulceration was defined as extension of contrast media beyond the vascular lumen into the surrounding plaque. Degree of stenosis in the symptomatic carotid artery was determined according to the NASCET criteria10 on multiplanar reformattting images perpendiculal to the central lumen line.

Plaque volume and plaque component proportions were measured with custom-made software, programmed in MeVisLab (MeVis Research, Bremen, Germany). Using this software, the components of the atherosclerotic plaque within regions of interest drawn on axial MDCTA images can be determined from their corresponding Hounsfield values using thresholds determined previously.11 The threshold for the distinction between fibrous tissue and lipidd-rich necrotic core (LR-NC) was set at 60 Hounsfield units. The threshold for distinguishing calcifications from fibrous tissue was set at 130 Hounsfield units; the value currently used for calcium scoring. Based on previous studies, it may be assumed that intraplaque hemorrhage, if present, would be classified as LR-NC12 or fibrous tissue.12

Plaque volume and plaque component volumes were automatically calculated from the number and dimensions of voxels for different ranges of Hounsfield unit values within the regions of interest (Figure 1). Plaque component proportions were calculated from plaque component volumes as a percentage of the plaque volume.

Statistical Analysis
Baseline population and plaque characteristics are presented as means±SD or number of patients (%). Differences were tested with χ² tests, Fisher exact tests, or Mann–Whitney tests when appropriate. For logistic regression analysis, continuous data were divided by 10 or 100, as indicated in the relevant tables.

The correlation between degree of stenosis and plaque volume was evaluated by calculation of the Spearman rank correlation coefficient. The associations between carotid plaque ulceration and degree of stenosis, plaque volume, and plaque component proportions were evaluated using logistic regression analysis. Two models were constructed. In model I, plaque characteristics were adjusted for age and sex. In model II, adjustments were made for age, sex, and degree of stenosis. Finally, in a stratified analysis, the associations between carotid plaque ulceration and plaque characteristics were evaluated in patients with low (0% to 49%), and with significant (≥50%) carotid stenosis, with adjustment for age, sex, and degree of stenosis. Probability values of ≤0.05 were considered statistically significant. All analyses were performed using SPSS 15.0 statistical package for Windows (SPSS Inc, Chicago, IL).

Results

Patients Characteristics
From the 346 evaluated patients, 185 patients with atherosclerotic plaque were included in all further analyses. Baseline characteristics of patients with and without atherosclerotic plaque ulceration in the symptomatic carotid artery are illustrated in Table 1. Atherosclerotic plaque ulceration in the symptomatic carotid artery was present in 38 (21%) patients. The prevalence of cardiovascular risk factors was not significantly different between the 2 groups.

Plaque Characteristics on MDCTA
Atherosclerotic plaque characteristics of patients with and without atherosclerotic plaque ulceration in the symptomatic carotid artery are illustrated in Table 2. Degree of stenosis was significantly higher in patients with plaque ulceration. In patients with carotid artery ulcerations, 19 had 0% to 49% stenosis, whereas the remaining 19 patients had ≥50% stenosis (Figure 2).

Plaque volume of ulcerated plaques was significantly larger as compared with nonulcerated plaques. A moderate correlation was observed between degree of stenosis and plaque volume (r=0.57; P=0.01). Ulcerated plaques contained a significantly larger LR-NC volume, fibrous tissue...
volume, and LR-NC proportion. Fibrous tissue proportion was significantly lower in ulcerated plaques as compared with nonulcerated plaques.

**Plaque Characteristics Associated With Plaque Ulceration on MDCTA**

Results of multivariable analyses relating plaque characteristics and plaque ulcerations are provided in Tables 3 and 4. After adjustment for age and sex (model I), degree of stenosis, plaque volume, and the LR-NC proportion were associated with plaque ulceration, whereas fibrous proportion was inversely associated with plaque ulceration. After adjustment for age, sex, and degree of stenosis (model II), plaque volume and the LR-NC proportion remained significantly associated with plaque ulceration, whereas the calcification proportion was inversely associated with plaque ulceration.

In a stratified analysis of patients with a low degree stenosis of 0% to 49% (n=144), the LR-NC proportion remained strongly associated with plaque ulceration, whereas the calcification proportion remained inversely associated with plaque ulceration. In patients with significant stenosis of ≥50% (n=41), plaque volume was associated with plaque ulceration, whereas a trend toward a significant association between the LR-NC proportion and plaque ulceration was observed.

**Discussion**

In the present study of patients with amaurosis fugax, transient ischemic attack, or ischemic stroke, half of the plaque ulcerations were identified in symptomatic carotid arteries with a low degree stenosis of 0% to 49%. Noninvasive carotid artery plaque analysis with MDCTA revealed that degree of stenosis, plaque volume, and the LR-NC proportion were associated with plaque ulceration in the symptomatic carotid artery. Of these plaque characteristics, the LR-NC proportion was most strongly associated with plaque ulceration. In contrast, the calcification proportion was inversely associated with plaque ulceration. The observed associations remained significant in patients with a low degree carotid stenosis of 0% to 49%. The present study...

is the first to evaluate the associations between plaque ulceration and plaque characteristics irrespective of the degree of stenosis.

Association of Atherosclerotic Plaque Characteristics With Ischemic Stroke

Several studies have evaluated the relationship of carotid artery plaque characteristics with ischemic stroke. In general, imaging studies with magnetic resonance and CT have identified positive associations between fibrous cap thickness, the size of the LR-NC, intraplaque hemorrhage, and the presence of carotid plaque surface disruption with ischemic stroke in cross-sectional and follow-up studies. Accordingly, in ultrasound studies, echolucent carotid plaques were associated with increased risk of cerebrovascular events. Echolucent plaques are known to have higher levels of lipid and hemorrhage compared with echogenic plaques, which contain more calcification and fibrous tissue. On the contrary, proportion of carotid plaque calcification is inversely related with plaque surface disruption. In addition, the presence of intraplaque hemorrhage as assessed with magnetic resonance is significantly associated with the presence of plaque ulceration on MDCTA. Plaque ulceration on conventional angiography in symptomatic carotid arteries with ≥50% stenosis was associated with the presence of intraplaque hemorrhage, large lipids, and less fibrous tissue in carotid endarterectomy specimens. Similarly, ultrasonographic examination of carotid arteries demonstrated a relationship between echolucency of stenotic plaques and plaque ulceration. However, conventional angiography and ultrasound provide no quantitative information on plaque volume. Therefore, only limited data are available on the relationship of plaque volume with plaque surface disruption as assessed using magnetic resonance.

MDCTA allows for fast and reliable evaluation of stenotic disease in extracranial and intracranial arteries and is widely available. The technique is effective in the detection of carotid plaque ulceration with a sensitivity and specificity of 94% and 99%, respectively. Furthermore, distinct plaque components, as well as plaque volume, can be quantified in good correlation with histology. In the present study, using MDCTA, the relationship between

plaque composition and plaque volume with plaque ulceration was evaluated in patients with a symptomatic carotid stenosis of ≥50% as well as in patients with a low degree of stenosis (0% to 49%). Interestingly, in line with previous reports, a substantial proportion of the plaque ulcerations were located in symptomatic carotid arteries with a low degree of stenosis. The association between the LR-NC proportion with plaque ulceration was significant in ischemic stroke patients with a low degree of stenosis (0% to 49%), whereas a trend toward significance was observed in patients with a stenosis of ≥50%. The inverse association observed between the calcification proportion and plaque ulceration was significant in patients with a low degree stenosis. Furthermore, only a weak correlation was observed between the degree of carotid artery stenosis and plaque volume on MDCTA. Importantly, plaque volume was associated with plaque ulceration, even after adjustment for the severity of stenosis. Overall, these findings demonstrate that the associations between plaque composition and volume with plaque ulcerations are present in ischemic stroke patients irrespective of the degree of the carotid plaque stenosis. In addition, an etiologic explanation is provided for the previously observed correlation of plaque characteristics with ischemic stroke events. Herein, a key role is suggested for plaque ulceration in the pathophysiological cascade between the development of a heterogeneous plaque and thromboembolic stroke. As a consequence, apart from degree of stenosis, assessment of carotid plaque composition and volume that predispose ulceration could contribute to risk stratification for plaque instability or stroke recurrence.

Study Limitations
First, the study has a cross-sectional design. Indeed, the prognostic value of plaque composition analysis with MDCTA and, more specifically, of the LR-NC proportion for the development of plaque ulceration and subsequent thromboembolic ischemic stroke should be confirmed in longitudinal serial imaging studies. Second, in the present study, the presence of intraplaque hemorrhage was not evaluated because plaque composition analysis software used in the present study has not been validated for differentiation of intraplaque hemorrhage. As a result, both LR-NC and fibrous tissue assessed with MDCTA may contain intraplaque hemorrhage if present in the plaque. Finally, plaque composition analysis can be performed on routine MDCTA scans used for carotid stenosis evaluation. Nevertheless, every MDCTA leads to ionizing radiation exposure. Therefore, repeated examinations should not be advocated.

Clinical and Research Implications
To our knowledge, the present study is the first to examine the associations between carotid plaque characteristics and carotid plaque ulceration in ischemic stroke patients with a ≥50% stenosis, as well as in those with a low degree stenosis of 0% to 49%. The LR-NC proportion was identified as the strongest determinant for plaque ulceration. The association between the LR-NC proportion and carotid plaque ulceration was independent of the degree of stenosis. Plaque composition analysis with MDCTA may prove useful for detection of rupture-prone plaques and could potentially improve risk stratification in ischemic stroke patients.

脛骨および目的：頭動脈の頭動脈プラック形成は、頭動脈狭窄率が50%以上の血管性脳中患者にみられる脛骨に在する大きな增大をもたらすコア（L.R.-NC）や、頭動脈の増大を伴う。本研究では、頭動脈狭窄率50%以上の頭動脈狭帯の血管性脳中患者の低い（0～49%）患者を対象に、頭動脈プラック形成とプラック性の関連を検討した。

方法：頭動脈狭帯にプラークが見られる患者（365例）を基準として、多発器CT血管造影（MDCTA）により、プラック性のある頭動脈プラックの有無、狭帯の程度、プラック形成形態について評価を行った。プラック形態と、プラックを構成するL.R.-NC、細線性線状、石灰化の比率を測定した。ロジスティック回帰分析を用いて、プラック形成とプラック性の関連を検討した。

結果：185例に頭動脈硬化性プラックが認められた。38例（21%）にプラック形成が認められ、うち半数は狭窄率が低かった（0～49%）。頭動脈の頭動脈形成プラックはプラックが多かった。

脛骨発症が予測する可能性がある。
