AHA/ASA Guideline

Guidelines for the Management of Aneurysmal Subarachnoid Hemorrhage
A Guideline for Healthcare Professionals From the American Heart Association/American Stroke Association

The American Academy of Neurology affirms the value of this statement as an educational tool for neurologists.

Endorsed by the American Association of Neurological Surgeons and Congress of Neurological Surgeons; and by the Society of NeuroInterventional Surgery

E. Sander Connolly, Jr, MD, FAHA, Chair; Alejandro A. Rabinstein, MD, Vice Chair; J. Ricardo Carhuapoma, MD, FAHA; Colin P. Derdeyn, MD, FAHA; Jacques Dion, MD, FRCPC; Randall T. Higashida, MD, FAHA; Brian L. Hoh, MD, FAHA; Catherine J. Kirkness, PhD, RN; Andrew M. Naidech, MD, MSPH; Christopher S. Ogilvy, MD; Aman B. Patel, MD; B. Gregory Thompson, MD; Paul Vespa, MD, FAAN; on behalf of the American Heart Association Stroke Council, Council on Cardiovascular Radiology and Intervention, Council on Cardiovascular Nursing, Council on Cardiovascular Surgery and Anesthesia, and Council on Clinical Cardiology

Purpose—The aim of this guideline is to present current and comprehensive recommendations for the diagnosis and treatment of aneurysmal subarachnoid hemorrhage (aSAH).

Methods—A formal literature search of MEDLINE (November 1, 2006, through May 1, 2010) was performed. Data were synthesized with the use of evidence tables. Writing group members met by teleconference to discuss data-derived recommendations. The American Heart Association Stroke Council’s Levels of Evidence grading algorithm was used to grade each recommendation. The guideline draft was reviewed by 7 expert peer reviewers and by the members of the Stroke Council Leadership and Manuscript Oversight Committees. It is intended that this guideline be fully updated every 3 years.

Results—Evidence-based guidelines are presented for the care of patients presenting with aSAH. The focus of the guideline was subdivided into incidence, risk factors, prevention, natural history and outcome, diagnosis, prevention of rebleeding, surgical and endovascular repair of ruptured aneurysms, systems of care, anesthetic management during repair, management of vasospasm and delayed cerebral ischemia, management of hydrocephalus, management of seizures, and management of medical complications.

Conclusions—aSAH is a serious medical condition in which outcome can be dramatically impacted by early, aggressive, expert care. The guidelines offer a framework for goal-directed treatment of the patient with aSAH. (Stroke. 2012;43:1711-1737.)

Key Words: AHA Scientific Statements ▪ aneurysm ▪ delayed cerebral ischemia ▪ diagnosis ▪ subarachnoid hemorrhage ▪ treatment ▪ vasospasm

The American Heart Association makes every effort to avoid any actual or potential conflicts of interest that may arise as a result of an outside relationship or a personal, professional, or business interest of a member of the writing panel. Specifically, all members of the writing group are required to complete and submit a Disclosure Questionnaire showing all such relationships that might be perceived as real or potential conflicts of interest.

Expert peer review of AHA Scientific Statements is conducted by the AHA Office of Science Operations. For more on AHA statements and guidelines development, visit http://my.americanheart.org/statements and select the “Policies and Development” link.

1711
To respond to the growing call for more evidenced-based medicine, the American Heart Association (AHA) commissions guidelines on various clinical topics and endeavors to keep them as current as possible. The prior aneurysmal subarachnoid hemorrhage (aSAH) guidelines, sponsored by the AHA Stroke Council, were previously issued in 1994 and 2009. The 2009 guidelines covered literature through November 1, 2006. The present guidelines primarily cover literature published between November 1, 2006, and May 1, 2010, but the writing group has strived to place these data in the greater context of the prior publications and recommendations. In cases in which new data covered in this review have resulted in a change in a prior recommendation, this is explicitly noted.

aSAH is a significant cause of morbidity and mortality throughout the world. Although the incidence of aSAH varies widely among populations, perhaps because of genetic differences, competing burden of disease, and issues of case ascertainment, at the very least, a quarter of patients with aSAH die, and roughly half of survivors are left with some persistent neurological deficit. That said, case-fatality rates appear to be falling, and increasing data suggest that early aneurysm repair, together with aggressive management of complications such as hydrocephalus and delayed cerebral ischemia (DCI), is leading to improved functional outcomes. These improvements underscore the need to continually reassess which interventions provide the greatest benefit to patients.

Although large, multicenter, randomized trial data confirming effectiveness are usually lacking for many of the interventions discussed, the writing group did its best to summarize the strength of the existing data and make practical recommendations that clinicians will find useful in the day-to-day management of aSAH. This review does not discuss the multitude of ongoing studies. Many of these can be found at http://www.strokecenter.org/trials/. The mechanism of reviewing the literature, compiling and analyzing the data, and determining the final recommendations to be made is identical to the 2009 version of this guideline.

The recommendations follow the AHA Stroke Council’s methods of classifying the level of certainty of the treatment effect and the class of evidence (Tables 1 and 2). All Class I recommendations are listed in Table 3. All new or revised recommendations are listed in Table 4.

### Incidence and Prevalence of aSAH

Considerable variation in the annual incidence of aSAH exists in different regions of the world. A World Health Organization study found a 10-fold variation in the age-adjusted annual incidence in countries in Europe and Asia, from 2.0 cases per 100,000 population in China to 22.5 cases per 100,000 in Finland. A later systematic review supported a high incidence of aSAH in Finland and Japan, a low incidence in South and Central America, and an intermediate incidence of 9.1 per 100,000 population in other regions. In a more recent systematic review of population-based studies, the incidence of aSAH ranged from 2 to 16 per 100,000. In that review, the pooled age-adjusted incidence rate of aSAH in low- to middle-income countries was found to be almost double that of high-income countries. Although some reports have suggested the incidence of aSAH in the United States to be 9.7 per 100,000, the 2003 Nationwide Inpatient Sample provided an annual estimate of 14.5 discharges for aSAH per 100,000 adults. Because death resulting from aSAH often occurs before hospital admission (an estimated 12% to 15% of cases), the true incidence of aSAH might be even higher. Although a number of population-based studies have indicated that the incidence of aSAH has remained relatively stable over the past 4 decades, a recent review that adjusted for age and sex suggested a slight decrease in incidence between 1950 and 2005 for regions other than Japan, South and Central America, and Finland. These data are consistent with studies that show that the incidence of aSAH increases with age, with a typical average age of onset in adults ≥50 years of age. aSAH is relatively uncommon in children; incidence rates increase as children get older, with incidence ranging from 0.18 to 2.0 per 100,000. The majority of studies also indicate a higher incidence of aSAH in women than in men. Most recent pooled figures report the incidence in women to be 1.24 (95% confidence interval, 1.09–1.42) times higher than in men. This is lower than a previous estimate of 1.6 (95% confidence interval, 1.1–2.3) for the years 1960 to 1994. Evidence of a sex-age effect on aSAH incidence has emerged from pooled study data, with a higher incidence reported in younger men (25–45 years of age), women between 55 and 85 years of age, and men >85 years of age. Differences in incidence of aSAH by race and ethnicity appear to exist.
Blacks and Hispanics have a higher incidence of aSAH than white Americans.\(^6,24,25\)

### Risk Factors for and Prevention of aSAH

Behavioral risk factors for aSAH include hypertension, smoking, alcohol abuse, and the use of sympathomimetic drugs (eg, cocaine). In addition to female sex (above), the risk of aSAH is increased by the presence of an unruptured cerebral aneurysm (particularly those that are symptomatic, larger in size, and located either on the posterior communicating artery or the vertebrobasilar system), a history of previous aSAH (with or without a residual untreated aneurysm), a history of familial aneurysms (at least 1 first-degree family member with an intracranial aneurysm, and especially if \( \geq 2 \) first-degree relatives are affected) and family history of aSAH,26,27 and certain genetic syndromes, such as autosomal dominant polycystic kidney disease and type IV Ehlers-Danlos syndrome.28,29 Novel findings reported since publication of the previous version of these guidelines include the following: (1) Aneurysms in the anterior circulation appear to be more prone to rupture in patients \( \geq 55 \) years of age, whereas posterior communicating aneurysms ruptured more frequently in men, and basilar artery aneurysm rupture is associated with lack of use of alcohol.30 (2) The size at which

### Table 1. Applying Classification of Recommendation and Level of Evidence

<table>
<thead>
<tr>
<th>Level A</th>
<th>Multiple populations evaluated*</th>
<th>Data derived from multiple randomized clinical trials or meta-analyses</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>LEVEL A</strong></td>
<td>Recommendation that procedure or treatment is useful/effective</td>
<td>Sufficient evidence from multiple randomized trials or meta-analyses</td>
</tr>
<tr>
<td><strong>LEVEL B</strong></td>
<td>Recommendation that procedure or treatment is useful/effective</td>
<td>Evidence from single randomized trial or nonrandomized studies</td>
</tr>
<tr>
<td><strong>LEVEL C</strong></td>
<td>Recommendation that procedure or treatment is useful/effective</td>
<td>Only expert opinion, case studies, or standard of care</td>
</tr>
</tbody>
</table>

A recommendation with Level of Evidence B or C does not imply that the recommendation is weak. Many important clinical questions addressed in the guidelines do not lend themselves to clinical trials. Although randomized trials are unavailable, there may be a very clear clinical consensus that a particular test or therapy is useful or effective.

*Data available from clinical trials or registries about the usefulness/efficacy in different subpopulations, such as sex, age, history of diabetes, history of prior myocardial infarction, history of heart failure, and prior aspirin use.

†For comparative effectiveness recommendations (Class I and IIa; Level of Evidence A and B only), studies that support the use of comparator verbs should involve direct comparisons of the treatments or strategies being evaluated.

---

Blacks and Hispanics have a higher incidence of aSAH than white Americans.\(^6,24,25\)
Table 2. Definition of Classes and Levels of Evidence Used in AHA Stroke Council Recommendations

Therapeutic recommendations

- **Level of Evidence A**
  - Data derived from multiple randomized clinical trials or meta-analyses

- **Level of Evidence B**
  - Data derived from a single randomized trial or nonrandomized studies

- **Level of Evidence C**
  - Consensus opinion of experts, case studies, or standard of care

Diagnostic recommendations

- **Level of Evidence A**
  - Data derived from multiple prospective cohort studies using a reference standard applied by a masked evaluator

- **Level of Evidence B**
  - Data derived from a single grade A study, or ≥1 case-control studies, or studies using a reference standard applied by an unmasked evaluator

- **Level of Evidence C**
  - Consensus opinion of experts

aneurysms rupture appears to be smaller in those patients with the combination of hypertension and smoking than in those with either risk factor alone.31 (3) Significant life events such as financial or legal problems within the past month may increase the risk of aSAH.32 (4) Aneurysm size >7 mm has been shown to be a risk factor for rupture.33 (5) There does not appear to be an increased risk of aSAH in pregnancy, delivery, and puerperium.34,35

Inflammation appears to play an important role in the pathogenesis and growth of intracranial aneurysms.56 Prominent mediators include the nuclear factor κ-light-chain enhancer of activated B cells (NF-κB),37 tumor necrosis factor, macrophages, and reactive oxygen species. Although there are no controlled studies in humans, 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statin)38 and calcium channel blockers may retard aneurysm formation through the inhibition of NF-κB and other pathways. Among the risk factors for aSAH, clearly attributable and modifiable risks are very low body mass index, smoking, and high alcohol consumption.31,39,40 Yet, despite marked improvements in the treatment of hypertension and hyperlipidemia and the decrease in rates of smoking over time, the incidence of aSAH has not changed appreciably in 30 years.16

It is possible that diet increases the risk of stroke in general and aSAH in particular. In an epidemiological study of Finnish smokers who were monitored for >13 years, increased consumption of yogurt (but not all dairy products) was associated with a higher risk of aSAH.51 Greater vegetable consumption is associated with a lower risk of stroke and aSAH.52 Higher coffee and tea consumption53 and higher magnesium consumption54 were associated with reduced risk of stroke overall but did not change the risk of aSAH.

Predicting the growth of an individual intracranial aneurysm and its potential for rupture in a given patient remains problematic. When followed up on magnetic resonance imaging, larger aneurysms (≥8 mm in diameter) tended to grow more over time,45 which implies a higher risk of rupture. Several characteristics of aneurysm morphology (such as a bottleneck shape46 and the ratio of size of aneurysm to parent vessel47,48) have been associated with rupture status, but how these might be applied to individual patients to predict future aneurysmal rupture is still unclear.35 Variability within each patient is unpredictable at this time, but such individual variability markedly changes the risk of aneurysm detection and rupture and may attenuate the benefits of routine screening in high-risk patients.49

Given such uncertainties, younger age, longer life expectancy, and higher rate of rupture all make treatment of unruptured aneurysms more likely to be cost-effective and reduce morbidity and mortality.50 Two large observational studies of familial aneurysms suggest that screening these patients may also be cost-effective in preventing aSAH and improving quality of life.26,27 Smaller studies have suggested that screening of those with 1 first-degree relative with aSAH may be justified as well, but it is far less clear whether patients who underwent treatment for a previous aSAH require ongoing screening.51,52 In the Cerebral Aneurysm Rerupture After Treatment (CARAT) study, recurrent aSAH was predicted by incomplete obliteration of the aneurysm and occurred a median of 3 days after treatment but rarely after 1 year.53 Repeated noninvasive screening at later times may not be cost-effective, increase life expectancy, or improve quality of life in unselected patients.54 Patients with adequately obliterated aneurysms after aSAH have a low risk of recurrent aSAH for at least 5 years,55,56 although some coiled aneurysms require retreatment.57

Risk Factors for and Prevention of aSAH: Recommendations

1. **Treatment of high blood pressure with antihypertensive medication is recommended to prevent ischemic stroke, intracerebral hemorrhage, and cardiac, renal, and other end-organ injury (Class I; Level of Evidence A).**

2. **Hypertension should be treated, and such treatment may reduce the risk of aSAH (Class I; Level of Evidence B).**

3. **Tobacco use and alcohol misuse should be avoided to reduce the risk of aSAH (Class I; Level of Evidence B).**
4. In addition to the size and location of the aneurysm and the patient’s age and health status, it might be reasonable to consider morphological and hemodynamic characteristics of the aneurysm when discussing the risk of aneurysm rupture (Class IIb; Level of Evidence B). (New recommendation)

5. Consumption of a diet rich in vegetables may lower the risk of aSAH (Class IIb; Level of Evidence B). (New recommendation)

6. It may be reasonable to offer noninvasive screening to patients with familial (at least 1 first-degree relative) aSAH and/or a history of aSAH to evaluate...
Table 4. New or Revised Recommendations

<table>
<thead>
<tr>
<th>New or Revised</th>
<th>Recommendation</th>

</tr>
</thead>
<tbody>
<tr>
<td>New</td>
<td>1. In addition to the size and location of the aneurysm and the patient’s age and health status, it might be reasonable to consider morphological and hemodynamic characteristics of the aneurysm when discussing the risk of aneurysm rupture.</td>
<td>Class IIb, Level B</td>
</tr>
<tr>
<td>New</td>
<td>2. Consumption of a diet rich in vegetables may lower the risk of aSAH.</td>
<td>Class IIb, Level B</td>
</tr>
<tr>
<td>New</td>
<td>3. After any aneurysm repair, immediate cerebrovascular imaging is generally recommended to identify remnants or recurrence of the aneurysm that may require treatment.</td>
<td>Class I, Level B</td>
</tr>
<tr>
<td>New</td>
<td>4. After discharge, it is reasonable to refer patients with aSAH for a comprehensive evaluation, including cognitive, behavioral, and psychosocial assessments.</td>
<td>Class IIa, Level B</td>
</tr>
<tr>
<td>New</td>
<td>5. CTA may be considered in the workup of aSAH. If an aneurysm is detected by CTA, this study may help guide the decision for the type of aneurysm repair, but if CTA is inconclusive, DSA is still recommended (except possibly in the instance of classic perimesencephalic SAH).</td>
<td>Class IIb, Level C</td>
</tr>
<tr>
<td>New</td>
<td>6. Magnetic resonance imaging (fluid-attenuated inversion recovery, proton density, diffusion-weighted imaging, and gradient echo sequences) may be reasonable for the diagnosis of SAH in patients with a nondiagnostic CT scan, although a negative result does not obviate the need for cerebrospinal fluid analysis.</td>
<td>Class IIb, Level C</td>
</tr>
<tr>
<td>New</td>
<td>7. DSA with 3-dimensional rotational angiography is indicated for detection of aneurysm in patients with aSAH (except when the aneurysm was previously diagnosed by a noninvasive angiogram) and for planning treatment (to determine whether an aneurysm is amenable to coiling or to expedite microsurgery).</td>
<td>Class I, Level B</td>
</tr>
<tr>
<td>New</td>
<td>8. Between the time of aSAH symptom onset and aneurysm obliteration, blood pressure should be controlled with a titratable agent to balance the risk of stroke, hypertension-related rebleeding, and maintenance of cerebral perfusion pressure.</td>
<td>Class I, Level B</td>
</tr>
<tr>
<td>New</td>
<td>9. The magnitude of blood pressure control to reduce the risk of rebleeding has not been established, but a decrease in systolic blood pressure to &lt;160 mm Hg is reasonable.</td>
<td>Class IIa, Level C</td>
</tr>
<tr>
<td>New</td>
<td>10. In the absence of a compelling contraindication, patients who undergo coiling or clipping of a ruptured aneurysm should have delayed follow-up vascular imaging (timing and modality to be individualized), and strong consideration should be given to retreatment, either by repeat coiling or microsurgical clipping, if there is a clinically significant (eg, growing) remnant.</td>
<td>Class I, Level B</td>
</tr>
<tr>
<td>New</td>
<td>11. Microsurgical clipping may receive increased consideration in patients presenting with large (≥50 mL) intraparenchymal hematomas and middle cerebral artery aneurysms. Endovascular clipping may receive increased consideration in the elderly (≥70 y of age), in those presenting with poor-grade WFNS classification (IVV) aSAH, and in those with aneurysms of the basilar apex.</td>
<td>Class IIb, Level C</td>
</tr>
<tr>
<td>New</td>
<td>12. Stenting of a ruptured aneurysm is associated with increased morbidity and mortality.</td>
<td>Class III, Level C</td>
</tr>
<tr>
<td>New</td>
<td>13. Annual monitoring of complication rates for surgical and interventional procedures is reasonable.</td>
<td>Class IIa, Level C</td>
</tr>
<tr>
<td>New</td>
<td>14. A hospital credentialing process to ensure that proper training standards have been met by individual physicians treating brain aneurysms is reasonable.</td>
<td>Class IIa, Level C</td>
</tr>
<tr>
<td>New</td>
<td>15. Prophylactic hypervolemia or balloon angioplasty before the development of angiographic spasm is not recommended.</td>
<td>Class III, Level B</td>
</tr>
<tr>
<td>New</td>
<td>16. Transcranial Doppler is reasonable to monitor for the development of arterial vasospasm.</td>
<td>Class IIa, Level B</td>
</tr>
<tr>
<td>New</td>
<td>17. Perfusion imaging with CT or magnetic resonance can be useful to identify regions of potential brain ischemia.</td>
<td>Class IIa, Level B</td>
</tr>
<tr>
<td>New</td>
<td>18. Weaning EVD over &gt;24 hours does not appear to be effective in reducing the need for ventricular shunting.</td>
<td>Class III, Level B</td>
</tr>
<tr>
<td>New</td>
<td>19. Routine fenestration of the lamina terminalis is not useful for reducing the rate of shunt-dependent hydrocephalus and therefore should not be routinely performed.</td>
<td>Class III, Level B</td>
</tr>
<tr>
<td>New</td>
<td>20. Aggressive control of fever to a target of normothermia by use of standard or advanced temperature modulating systems is reasonable in the acute phase of aSAH.</td>
<td>Class IIa, Level B</td>
</tr>
<tr>
<td>New</td>
<td>21. The use of packed red blood cell transfusion to treat anemia might be reasonable in patients with aSAH who are at risk of cerebral ischemia. The optimal hemoglobin goal is still to be determined.</td>
<td>Class IIb, Level B</td>
</tr>
<tr>
<td>New</td>
<td>22. Heparin-induced thrombocytopenia and deep venous thrombosis are relatively frequent complications after aSAH. Early identification and targeted treatment are recommended, but further research is needed to identify the ideal screening paradigms.</td>
<td>Class I, Level B</td>
</tr>
<tr>
<td>Revised</td>
<td>1. For patients with an unavoidable delay in obliteration of aneurysm, a significant risk of rebleeding, and no compelling medical contraindications, short-term (&lt;72 hours) therapy with tranexamic acid or aminocaproic acid is reasonable to reduce the risk of early aneurysm rebleeding.</td>
<td>Class IIa, Level B</td>
</tr>
<tr>
<td>Revised</td>
<td>2. Determination of aneurysm treatment, as judged by both experienced cerebrovascular surgeons and endovascular specialists, should be a multidisciplinary decision based on characteristics of the patient and the aneurysm.</td>
<td>Class I, Level C</td>

</table>

(Continued)
for de novo aneurysms or late regrowth of a treated aneurysm, but the risks and benefits of this screening require further study (Class IIb; Level of Evidence B).

7. After any aneurysm repair, immediate cerebral vascular imaging is generally recommended to identify remnants or recurrence of the aneurysm that may require treatment (Class I; Level of Evidence B). (New recommendation)

Natural History and Outcome of aSAH

Although the case fatality of aSAH remains high worldwide, mortality rates from aSAH appear to have declined in industrialized nations over the past 25 years. One study in the United States reported a decrease of ≈1% per year from 1979 to 1994. Others have shown that case fatality rates decreased from 57% in the mid-1970s to 42% in the mid-1980s, whereas rates from the mid-1980s to 2002 are reported to be anywhere from 26% to 36%. Regional variations become apparent when numbers from different studies are compared. The median mortality rate in epidemiological studies from the United States has been 32% versus 43% to 44% in Europe and 27% in Japan. These numbers are based on studies that did not always fully account for cases of prehospital death. This is an important consideration because the observed decrease in case fatality is related to improvements in survival among hospitalized patients with aSAH.

The mean age of patients presenting with aSAH is increasing, which has been noted to have a negative impact on survival rates. Sex and racial variations in survival may also play a role in the variable rates, with some studies suggesting higher mortality in women than in men and higher mortality in blacks, American Indians/Alaskan Natives, and Asians/Pacific Islanders than in whites.

Available population-based studies offer much less information about the functional outcome of survivors. Rates of persistent dependence of between 8% and 20% have been reported when the modified Rankin Scale is used. Although not population based, trial data show a similar picture, with 12% of patients in the International Subarachnoid Aneurysm Trial (ISAT) showing significant lifestyle restrictions (modified Rankin Scale 3) and 6.5% being functionally dependent (modified Rankin Scale score of 4–5) 1 year after aSAH. Furthermore, scales that are relatively insensitive to cognitive impairment, behavioral changes, social readjustment, and energy level may substantially underestimate the effect of aSAH on the function and quality of life of surviving patients. Multiple studies using diverse designs have consistently demonstrated that intellectual impairment is very prevalent after aSAH. Although cognitive function tends to improve over the first year, global cognitive impairment is still present in 20% of aSAH patients and is associated with poorer functional recovery and lower quality of life. Cognitive deficits and functional decline are often compounded by mood disorders (anxiety, depression), fatigue, and sleep disturbances. Therefore, scales assessing well-being and quality of life can be particularly useful in the integral assessment of patients with aSAH, even among those who regain functional independence. Behavioral and psychosocial difficulties, as well as poor physical and mental endurance, are some of the most commonly encountered factors accounting for the inability of otherwise independent patients to return to their previous occupations.

Much remains to be learned about the causes of cognitive and functional deficits after aSAH and the best methods to assess intellectual outcome and functional recovery in these patients. The severity of clinical presentation is the strongest prognostic indicator in aSAH. Initial clinical severity can be
reliably categorized by use of simple validated scales, such as the Hunt and Hess and World Federation of Neurological Surgeons scales.69,70 Aneurysm rebleeding is another major predictor of poor outcome, as discussed in a later section. Other factors predictive of poor prognosis include older age, preexisting severe medical illness, global cerebral edema on computed tomography (CT) scan, intraventricular and intracerebral hemorrhage, symptomatic vasospasm, delayed cerebral infarction (especially if multiple), hyperglycemia, fever, anemia, and other systemic complications such as pneumonia and sepsis.71–77 Certain aneurysm factors, such as size, location, and complex configuration, may increase the risk of periprocedural complications and affect overall prognosis.78 Treatment in high-volume centers with availability of neurosurgical and endovascular services may be associated with better outcomes.79–81

Natural History and Outcome of aSAH: Recommendations

1. The initial clinical severity of aSAH should be determined rapidly by use of simple validated scales (eg, Hunt and Hess, World Federation of Neurological Surgeons), because it is the most useful indicator of outcome after aSAH (Class I; Level of Evidence B).

2. The risk of early aneurysm rebleeding is high, and rebleeding is associated with very poor outcomes. Therefore, urgent evaluation and treatment of patients with suspected aSAH is recommended (Class I; Level of Evidence B).

3. After discharge, it is reasonable to refer patients with aSAH for a comprehensive evaluation, including cognitive, behavioral, and psychosocial assessments (Class IIa; Level of Evidence B). (New recommendation)

Clinical Manifestations and Diagnosis of aSAH

The clinical presentation of aSAH is one of the most distinctive in medicine. The hallmark of aSAH in a patient who is awake is the complaint “the worst headache of my life,” which is described by ≈80% of patients who can give a history.82 This headache is characterized as being extremely sudden and immediately reaching maximal intensity (thunderclap headache). A warning or sentinel headache that precedes the aSAH-associated ictus is also reported by 10%–43% of patients.83,84 This sentinel headache increases the odds of early rebleeding 10-fold.85 Most intracranial aneurysms remain asymptomatic until they rupture. aSAH can occur during physical exertion or stress.86 Nevertheless, in a review of 513 patients with aSAH, the highest incidence of rupture occurred while patients were engaged in their daily routines, in the absence of strenuous physical activity.87 The onset of headache may be associated with ≥1 additional signs and symptoms, including nausea and/or vomiting, stiff neck, photophobia, brief loss of consciousness, or focal neurological deficits (including cranial nerve palsies). In a retrospective study of 109 patients with proven aSAH, headache was present in 74%, nausea or vomiting in 77%, loss of consciousness in 53%, and nuchal rigidity in 35%.88 As many as 12% of patients die before receiving medical attention.

Despite the classic presentation of aSAH, individual findings occur inconsistently, and because the type of headache from aSAH is sufficiently variable, misdiagnosis or delayed diagnosis is common. Before 1985, misdiagnosis of aSAH occurred in as many as 64% of cases, with more recent data suggesting a misdiagnosis rate of ≈12%.89,90 Misdiagnosis was associated with a nearly 4-fold higher likelihood of death or disability at 1 year in patients with minimal or no neurological deficit at the initial visit.89 The most common diagnostic error is failure to obtain a noncontrast head CT scan.89,91–93 In a small subset of patients, a high degree of suspicion based on clinical presentation will lead to the correct diagnosis despite normal head CT and cerebrospinal fluid test results, as shown in a recent study in which 1.4% of patients were diagnosed with aSAH only after vascular imaging techniques were used.94

Patients may report symptoms consistent with a minor hemorrhage before a major rupture, which has been called a sentinel bleed or warning leak.83,84 The majority of these minor hemorrhages occur within 2 to 8 weeks before overt aSAH. The headache associated with a warning leak is usually milder than that associated with a major rupture, but it may last a few days.95,96 Nausea and vomiting may occur, but meningismus is uncommon after a sentinel hemorrhage. Among 1752 patients with aneurysm rupture from 3 series, 340 (19.4%; range, 15%–37%) had a history of a sudden severe headache before the event that led to admission.92,95,97 The importance of recognizing a warning leak cannot be overemphasized. Headache is a common presenting chief complaint in the emergency department, and aSAH accounts for only 1% of all headaches evaluated in the emergency department.92 Therefore, a high index of suspicion is warranted, because diagnosis of the warning leak or sentinel hemorrhage before a catastrophic rupture may be lifesaving.93 Seizures may occur in up to 20% of patients after aSAH, most commonly in the first 24 hours and more commonly in aSAH associated with intracerebral hemorrhage, hypertension, and middle cerebral and anterior communicating artery aneurysms.98–99

Noncontrast head CT remains the cornerstone of diagnosis of aSAH; since publication of the previous version of these guidelines,1,2 there have been only minor changes in imaging technology for this condition. The sensitivity of CT in the first 3 days after aSAH remains very high (close to 100%), after which it decreases moderately during the next few days.2,100 After 5 to 7 days, the rate of negative CT increases sharply, and lumbar puncture is often required to show xanthochromia. However, advances in magnetic resonance imaging of the brain, particularly the use of fluid-attenuated inversion recovery, proton density, diffusion-weighted imaging, and gradient echo sequences,101–103 can often allow the diagnosis of aSAH to be made when a head CT scan is negative and there is clinical suspicion of aSAH, possibly avoiding the need for lumbar puncture. The role of magnetic resonance imaging in perimesencephalic aSAH is controversial.104 Indications for magnetic resonance angiography in aSAH are still few because of limitations with routine
availability, logistics (including difficulty in scanning acutely ill patients), predisposition to motion artifact, patient compliance, longer study time, and cost. Aneurysms <3 mm in size continue to be unreliably demonstrated on computed tomographic angiography (CTA),105,106 and this generates continued controversy in the case of CTA-negative aSAH.107 In cases of perimesencephalic subarachnoid hemorrhage (SAH), some authors claim that a negative CTA result is sufficient to rule out aneurysmal hemorrhage and that cerebral angiography is not required, but this is controversial. In 1 study, the overall interobserver and intraobserver agreement for nonaneurysmal perimesencephalic hemorrhage was good, but there was still a level of disagreement among observers, which suggests that clinicians should be cautious when deciding whether to pursue follow-up imaging.108 In another study,109 a negative CTA result reliably excluded aneurysms when head CT showed the classic perimesencephalic SAH pattern or no blood. Digital subtraction angiography (DSA) was indicated if there was a diffuse aneurysmal pattern of aSAH, and repeat delayed DSA was required if the initial DSA findings were negative, which led to the detection of a small aneurysm in 14% of cases. When the blood is located in the sulci, CTA should be scrutinized for vasculitis, and DSA is recommended for confirmation.109 Others have shown that CTA may not reveal small aneurysms and that 2- and 3-dimensional cerebral angiography should be performed, especially when the hemorrhage is accompanied by loss of consciousness.110 In cases of diffuse aSAH pattern, most agree that negative CTA should be followed by 2- and 3-dimensional cerebral angiography. In older patients with degenerative vascular diseases, CTA can replace catheter cerebral angiography in most cases if the image quality is excellent and analysis is performed carefully.111 Overlying bone can be problematic with CTA, especially at the skull base. A new technique, CTA-MMBE (multisection CTA combined with matched mask bone elimination), is accurate in detecting intracranial aneurysms in any projection without superimposed bone.112 CTA-MMBE has limited sensitivity in detecting very small aneurysms. The data suggest that DSA and 3-dimensional rotational angiography can be limited to the vessel harboring the ruptured aneurysm before endovascular treatment after detection of a ruptured aneurysm with CTA. Another new technique, dual-energy CTA, has diagnostic image quality at a lower radiation dose than digital subtraction CTA and high diagnostic accuracy compared with 3-dimensional DSA (but not 2-dimensional DSA) in the detection of intracranial aneurysms.113

Cerebral angiography is still widely used in the investigation of aSAH and the characterization of ruptured cerebral aneurysms. Although CTA is sometimes considered sufficient on its own when an aneurysm will be treated with surgical clipping,114 substantial controversy remains about the ability of CTA to determine whether or not an aneurysm is amenable to endovascular therapy.115–120 In 1 series,115 95.7% of patients with aSAH were referred for treatment on the basis of CTA. In 4.4% of patients, CTA did not provide enough information to determine the best treatment, and those patients required DSA; 61.4% of patients were referred to endovascular treatment on the basis of CTA; and successful coiling was achieved in 92.6%. The authors concluded that CTA with a 64-slice scanner is an accurate tool for detecting and characterizing aneurysms in acute aSAH and that CTA is useful in deciding whether to coil or clip an aneurysm.115 Partial volume averaging phenomena may artificially widen the aneurysmal neck and may lead to the erroneous conclusion that an aneurysm cannot be treated by endovascular coiling. This controversy is likely caused by the different technological specifications (16- versus 64-detector rows), slice thickness, and data processing algorithms of various CT systems, which have different spatial resolutions. Three-dimensional cerebral angiography is more sensitive for detecting aneurysms than 2-dimensional angiography.121,122 The combination of 3- and 2-dimensional cerebral angiography usually provides the best morphological depiction of aneurysm anatomy with high spatial resolution, and it is, of course, always used in preparation for endovascular therapy.

Flat-panel volumetric CT is a relatively recent development that allows the generation of CT-like images from a rotational 3-dimensional spin of the x-ray gantry in the angiography room. For the moment, it has no substantial role in the initial diagnosis of aSAH because its spatial and contrast resolutions are not high enough; however, this technology can be used intraprocedurally during embolizations to rule out hydrocephalus.124 Recently, radiation dose has emerged as an important and worrisome consideration for patients with SAH.125,126 The combination of noncontrast head CT for the diagnosis of aSAH, confirmation of ventriculostomy placement, investigation of neurological changes, CTA for aneurysmal diagnosis, CTA and CT perfusion for recognition of vasospasm, and catheter cerebral angiography for aneurysm embolization and then for endovascular therapy of vasospasm can result in substantial radiation doses to the head, with possible risk of radiation injury, such as scalp erythema and alopecia. Although some or all of these radiological examinations are often necessary, efforts need to be made to reduce the amount of radiation exposure in patients with aSAH whenever possible.

Clinical Manifestations and Diagnosis of aSAH: Recommendations

1. aSAH is a medical emergency that is frequently misdiagnosed. A high level of suspicion for aSAH should exist in patients with acute onset of severe headache (Class I; Level of Evidence B).

2. Acute diagnostic workup should include noncontrast head CT, which, if nondiagnostic, should be followed by lumbar puncture (Class I; Level of Evidence B).

3. CTA may be considered in the workup of aSAH. If an aneurysm is detected by CTA, this study may help guide the decision for type of aneurysm repair, but if CTA is inconclusive, DSA is still recommended (except possibly in the instance of classic perimesencephalic aSAH) (Class IIb; Level of Evidence C). (New recommendation)

4. Magnetic resonance imaging (fluid-attenuated inversion recovery, proton density, diffusion-weighted imaging, and gradient echo sequences) may be reasonable for the diagnosis of aSAH in patients with a nondiagnostic CT scan, although a negative result
Aneurysm rebleeding is associated with very high mortality and poor prognosis for functional recovery in survivors. The risk of rebleeding is maximal in the first 2 to 12 hours, with reported rates of occurrence between 4% and 13.6% within the first 24 hours. In fact, more than one third of rebleeds occur within 3 hours and nearly half within 6 hours of symptom onset, and early rebleeding is associated with worse outcome than later rebleeding. Factors associated with aneurysm rebleeding include longer time to aneurysm treatment, worse neurological status on admission, initial loss of consciousness, previous sentinel headaches (severe headaches lasting >1 hour that do not lead to the diagnosis of aSAH), larger aneurysm size, and possibly systolic blood pressure >160 mm Hg. Genetic factors, although related to the occurrence of intracranial aneurysms, do not appear to be related to an increased incidence of rebleeding. Early treatment of the ruptured aneurysm can reduce the risk of rebleeding. Among patients who present in a delayed manner and during the vasospasm window, delayed obliteration of aneurysm is associated with a higher risk of rebleeding than early obliteration of aneurysm.

There is general agreement that acute hypertension should be controlled after aSAH and until aneurysm obliteration, but parameters for blood pressure control have not been defined. A variety of titratable medications are available. Nicardipine may give smoother blood pressure control than labetalol and sodium nitroprusside, although data showing different clinical outcomes are lacking. Although lowering cerebral perfusion pressure may lead to cerebral ischemia, a cohort study of neurologically critically ill patients did not find an association between use of nicardipine and reduced brain oxygen tension. Clevidipine, a very short-acting calcium channel blocker, is another option for acute control of hypertension, but data for aSAH are lacking at this time.

Antifibrinolytic therapy has been shown to reduce the incidence of aneurysm rebleeding when there is a delay in aneurysm obliteration. One referral center instituted a policy of short-term use of aminocaproic acid to prevent rebleeding during patient transfer. Such use led to a decreased incidence in rebleeding without increasing the risk of DCI, but 3-month clinical outcomes were not affected. There was an increased risk of deep venous thrombosis but not pulmonary embolism. Neither aminocaproic acid nor tranexamic acid is approved by the US Food and Drug Administration for prevention of aneurysm rebleeding.

Medical Measures to Prevent Rebleeding After aSAH

Aneurysm rebleeding is associated with very high mortality and poor prognosis for functional recovery in survivors. The risk of rebleeding is maximal in the first 2 to 12 hours, with reported rates of occurrence between 4% and 13.6% within the first 24 hours. In fact, more than one third of rebleeds occur within 3 hours and nearly half within 6 hours of symptom onset, and early rebleeding is associated with worse outcome than later rebleeding. Factors associated with aneurysm rebleeding include longer time to aneurysm treatment, worse neurological status on admission, initial loss of consciousness, previous sentinel headaches (severe headaches lasting >1 hour that do not lead to the diagnosis of aSAH), larger aneurysm size, and possibly systolic blood pressure >160 mm Hg. Genetic factors, although related to the occurrence of intracranial aneurysms, do not appear to be related to an increased incidence of rebleeding. Early treatment of the ruptured aneurysm can reduce the risk of rebleeding. Among patients who present in a delayed manner and during the vasospasm window, delayed obliteration of aneurysm is associated with a higher risk of rebleeding than early obliteration of aneurysm.

There is general agreement that acute hypertension should be controlled after aSAH and until aneurysm obliteration, but parameters for blood pressure control have not been defined. A variety of titratable medications are available. Nicardipine may give smoother blood pressure control than labetalol and sodium nitroprusside, although data showing different clinical outcomes are lacking. Although lowering cerebral perfusion pressure may lead to cerebral ischemia, a cohort study of neurologically critically ill patients did not find an association between use of nicardipine and reduced brain oxygen tension. Clevidipine, a very short-acting calcium channel blocker, is another option for acute control of hypertension, but data for aSAH are lacking at this time.

Antifibrinolytic therapy has been shown to reduce the incidence of aneurysm rebleeding when there is a delay in aneurysm obliteration. One referral center instituted a policy of short-term use of aminocaproic acid to prevent rebleeding during patient transfer. Such use led to a decreased incidence in rebleeding without increasing the risk of DCI, but 3-month clinical outcomes were not affected. There was an increased risk of deep venous thrombosis but not pulmonary embolism. Neither aminocaproic acid nor tranexamic acid is approved by the US Food and Drug Administration for prevention of aneurysm rebleeding.

Medical Measures to Prevent Rebleeding After aSAH: Recommendations

1. Between the time of aSAH symptom onset and aneurysm obliteration, blood pressure should be controlled with a titratable agent to balance the risk of stroke, hypertension-related rebleeding, and maintenance of cerebral perfusion pressure. (Class I; Level of Evidence B). (New recommendation)

2. The magnitude of blood pressure control to reduce the risk of rebleeding has not been established, but a decrease in systolic blood pressure to <160 mm Hg is reasonable. (Class IIa; Level of Evidence C). (New recommendation)

3. For patients with an unavoidable delay in obliteration of aneurysm, a significant risk of rebleeding, and no compelling medical contraindications, short-term (<72 hours) therapy with tranexamic acid or aminocaproic acid is reasonable to reduce the risk of early aneurysm rebleeding. (Class IIa; Level of Evidence B). (Revised recommendation from previous guidelines)

Surgical and Endovascular Methods for Treatment of Ruptured Cerebral Aneurysms

Microsurgical clip obliteration of intracranial aneurysms was the primary modality of treatment before 1991, when Guglielm first described occlusion of an aneurysm by an endovascular approach with electrolytically detachable coils. With advancements in both microsurgical and endovascular approaches, algorithms to determine the proper patient population and aneurysm characteristics for each treatment are continually undergoing refinement. The only multicenter randomized trial comparing microsurgical and endovascular repair, ISAT, randomized 2143 of 9559 screened patients with aSAH across 42 neurosurgical centers. For a patient to be considered eligible for the trial, neurosurgeons and interventionalists had to agree that the aneurysm was comparably suitable for treatment with either modality. Primary outcomes included death or dependent living, and secondary outcomes included risk of seizures and risk of rebleeding. Initial 1-year outcomes revealed a reduction in death and disability from 31% in the microsurgery arm to 24% in the endovascular arm (relative risk reduction, 24%). This difference was mainly driven by a decrease in the rate of disability among survivors 16% in the endovascular arm and 22% in the craniotomy arm) and was likely attributable at least in part to the greater incidence of technical complications in the clipping (19%) versus the coiling (8%) arms and the longer time needed to secure the aneurysm.

The risk of epilepsy and significant cognitive decline was also reduced in the endovascular group, but the incidence of late rebleeding (2.9% after endovascular repair versus 0.9% after open surgery) was higher in the endovascular arm, and only 58% of coiled aneurysms were completely obliterated compared with 81% of clipped aneurysms. A large retrospective analysis found that the rate of incomplete occlusion and subsequent aneurysm recurrence depended critically on neck diameter and dome size. It can also be difficult to achieve complete obliteration in very small aneurysms (<3 mm), with 1 study
reporting no coils deployed in 5% of cases, residual dome filling or a neck remnant in 30%, and a higher procedural complication rate than in larger aneurysms.144

Although the complete obliteration rate can be increased by the addition of a high-porosity stent, this has been associated with an increased risk of complications, especially in patients with SAH, in large part because of the need for perioperative dual-antiplatelet therapy to prevent arterial thromboembolism.145 Whether low-porosity flow-diverting stents with or without coils represent a better option for many or most of those presenting with SAH from saccular aneurysms remains to be studied, but these stents make more conceptual sense for use in the patient with a dissecting aneurysm, in whom vessel sacrifice is not an option and microsurgical solutions carry higher risk.

Another approach to increasing complete obliteration rates involves the deployment of biologically active rather than pure platinum coils.146 Although uncontrolled studies suggest a potential reduction in the risk of recurrence, these data are preliminary and have yet to be confirmed in prospective controlled trials.147,148 Thus, although the short-term efficacy of endovascular coil obliteration is well established compared with microsurgical approaches, close long-term surveillance continues to be warranted, because durability remains a significant concern.149

Given this delicate balance between safety and durability, there have been multiple efforts to identify subgroups of patients who might be best treated with endovascular or microsurgical techniques. Although the quality of the data is modest, most agree that with current endovascular technology, middle cerebral artery aneurysms can be difficult to treat with coil embolization, and in this location, surgical treatment has tended to yield more favorable results.146,150–152 Although some have suggested that older patients are ideal candidates for coilng rather than clipping, data on this population are sparse and at times conflicting.141,153,154 Although patients presenting with an intraparenchymal hematoma >50 mL have a higher incidence of unfavorable outcome, hematoma evacuation within <3.5 hours has been shown to improve outcome in this subgroup and argues in favor of microsurgery for most patients with large parenchymal clots.155 By contrast, patients presenting during the vasospasm period, especially those with confirmed vasospasm, may be better treated with endovascular techniques, depending on the anatomy of the aneurysm and its relationship to the spasm.150 Patients presenting with poor clinical grade appear to benefit more from endovascular clipping, especially if they are also elderly, because advanced age renders long-term durability less important.156 Still, it is critical that patients with poor clinical grade be treated in centers where both modalities are available.157

Endovascular treatment of posterior circulation aneurysms has been gaining widespread acceptance based on several observational studies. A meta-analysis revealed that the mortality from clipping of a basilar bifurcation aneurysm was 0.9%, and the risk of permanent complications was 5.4%.158 More recently, with regard to treatment of posterior circulation aneurysms, the mortality and morbidity in 112 ruptured aneurysms was 3.7% and 9.4%, respectively.159 These data have led to an increasing tendency toward clipping ruptured posterior circulation aneurysms. One study that compared clipping versus coiling of basilar apex aneurysm (44 patients in each treatment arm) found a poor outcome rate of 11% in the endovascular treatment group versus 30% in the surgical group. In that study, the main difference was the rate of ischemia and hemorrhage during the surgical intervention. The rates of recurrent hemorrhage and delayed ischemia were actually similar in both groups.159

Incomplete aneurysm occlusion and recurrent aneurysm filling from progressive coil compaction are particularly difficult challenges encountered with endovascular treatment of basilar artery aneurysms. In a study of 41 posterior circulation aneurysms, 35 (85%) had complete or near-complete immediate angiographic occlusion. The follow-up time frame for this study was 17 months, and of the 29 patients for whom follow-up was obtained, those with completely occluded aneurysms did not reveal any compaction. In the remaining patients who had near-complete occlusion, 47% had experienced recanalization, with 1 patient experiencing a rehemorrhage.160 On the basis of these findings, closer follow-up with sequential DSA is needed in patients who undergo coiling of posterior circulation aneurysms, particularly those who do not exhibit complete occlusion on immediate follow-up angiography.

Surgical and Endovascular Methods of Treatment of Ruptured Cerebral Aneurysms: Recommendations

1. Surgical clipping or endovascular coiling of the ruptured aneurysm should be performed as early as feasible in the majority of patients to reduce the rate of rebleeding after aSAH (Class I; Level of Evidence B).

2. Complete obliteration of the aneurysm is recommended whenever possible (Class I; Level of Evidence B).

3. Determination of aneurysm treatment, as judged by both experienced cerebrovascular surgeons and endovascular specialists, should be a multidisciplinary decision based on characteristics of the patient and the aneurysm (Class I; Level of Evidence C). (Revised recommendation from previous guidelines)

4. For patients with ruptured aneurysms judged to be technically amenable to both endovascular coiling and neurosurgical clipping, endovascular coiling should be considered (Class I; Level of Evidence B). (Revised recommendation from previous guidelines)

5. In the absence of a compelling contraindication, patients who undergo coiling or clipping of a ruptured aneurysm should have delayed follow-up vascular imaging (timing and modality to be individualized), and strong consideration should be given to retreatment, either by repeat coiling or microsurgical clipping, if there is a clinically significant (eg, growing) remnant (Class I; Level of Evidence B). (New recommendation)

6. Microsurgical clipping may receive increased consideration in patients presenting with large (>50 mL) intraparenchymal hematomas and middle cerebral artery aneurysms. Endovascular clipping may receive increased consideration in the elderly (>70 years of age), in those presenting with poor-grade
(World Federation of Neurological Surgeons classification IV/N) aSAH, and in those with aneurysms of the basilar apex (Class IIb; Level of Evidence C). (New recommendation)

7. Stenting of a ruptured aneurysm is associated with increased morbidity and mortality, and should only be considered when less risky options have been excluded (Class III; Level of Evidence C). (New recommendation)

Hospital Characteristics and Systems of Care
In a US study of 31,476 nontraumatic cases of aSAH from 2003, definitive aneurysm repair was delivered in fewer than one third of cases. That said, the adjusted odds of definitive repair were significantly higher in urban teaching hospitals than in urban nonteaching hospitals (odds ratio, 1.62) or rural hospitals (odds ratio, 3.08).7 In another study from 1993 to 2003, teaching status and larger hospital size were associated with higher charges and longer stay but also with better outcomes (P<0.05) and lower mortality rates (P<0.05), especially in patients who underwent aneurysm clipping (P<0.01). Endovascular treatment, which was more often used in the elderly, was also associated with significantly higher mortality rates in smaller hospitals (P<0.001) and steadily increasing morbidity rates (45%). Large academic centers were associated with better results, particularly for surgical clip placement.161 Prior studies have also indicated that 82% of US hospitals admitted <19 patients with aSAH annually, and the 30-day mortality rate was significantly higher in hospitals that admitted <10 patients with aSAH versus >35 patients with aSAH (39% versus 27%; odds ratio, 1.4).80

Two factors associated with better outcomes were greater use of endovascular services and a higher percentage of patients transferred from other hospitals.79–81 Institutions that used endovascular coil embolization more frequently had lower in-hospital mortality rates, a 9% reduction in risk for every 10% of cases treated. In addition, there was a 16% reduction in risk of in-hospital death at institutions that used interventional therapies such as balloon angioplasty to treat arterial vasospasm.2,81,162 Therefore, hospital treatment volumes and availability of both endovascular and neurological intensive care services at hospitals are important determinants of improved outcomes in aSAH.163 In addition, a cost-utility analysis estimated that transferring a patient with aSAH from a low- to a high-volume hospital would result in a gain of 1.6 quality-adjusted life-years at a cost of $10,548.162,163

Although 1 study suggested that care was uniformly delivered within an institution when weekend and weekday admissions were compared,164 others have shown that intensive care specialists followed evidence-based recommendations very inconsistently, and these variations in practice did not depend on the quality of the supporting data.165 Significant practice differences were noted between respondents from North America and Europe and between those working in high- and low-volume centers. Thus, the study demonstrated that the practices of intensive care unit physicians treating aSAH are heterogenous and often at variance with available evidence.165

One recent effort to increase the uniformity of care is the development of an Accreditation Council on Graduate Medical Education–approved fellowship training program for endovascular surgical neuroradiology.166 Another effort is legislation or regulation in >10 states that defines elements of comprehensive stroke centers and their role in networks and stroke systems of care. The Brain Attack Coalition paper that proposed the establishment of these centers included management of aSAH in its scope.167 From the endovascular perspective, this expertise includes the ability to treat patients with intracranial aneurysms, SAH-induced vasospasm, brain arteriovenous malformations, and ischemic stroke. Other important required elements of these centers are vascular neurosurgical expertise, dedicated intensive care units, and 24/7 access to advanced neuroimaging. The rationale for comprehensive stroke centers is based on the success of similar models for trauma.

Hospital Characteristics and Systems of Care: Recommendations

1. Low-volume hospitals (eg, <10 aSAH cases per year) should consider early transfer of patients with aSAH to high-volume centers (eg, >35 aSAH cases per year) with experienced cerebrovascular surgeons, endovascular specialists, and multidisciplinary neuro-intensive care services (Class I; Level of Evidence B). (Revised recommendation from previous guidelines)

2. Annual monitoring of complication rates for surgical and interventional procedures is reasonable (Class IIa; Level of Evidence C). (New recommendation)

3. A hospital credentialing process to ensure that proper training standards have been met by individual physicians treating brain aneurysms is reasonable (Class IIa; Level of Evidence C). (New recommendation)

Anesthetic Management During Surgical and Endovascular Treatment
The general goals of anesthetic management involve hemodynamic control to minimize the risk of aneurysm rerupture and strategies to protect the brain against ischemic injury. Although induced hypotension has been used in the past to prevent aneurysm rupture, data suggest that there could be potential harm, with an increased risk of early and delayed neurological deficits.168,169 A retrospective study suggests that a decrease in mean arterial pressure of >50% is associated with poor outcome; however, after adjustment for age, this association was no longer statistically significant.170 In patients undergoing cerebral aneurysm surgery, intraoperative hyperglycemia has been associated with long-term decline in cognition and gross neurological function.171 These associations are seen at levels of hyperglycemia commonly encountered in practice, with increased risk of alterations in cognition with glucose concentrations >129 mg/dL and neurological deficits with glucose concentrations >152 mg/dL.172 Numerous pharmacological agents have been used to promote cerebral protection during cerebral aneurysm sur-
gery,172–181 but none have been clearly shown to improve outcome.

Systemic hypothermia has been used in several clinical settings, including head injury, ischemic stroke, and circulatory arrest, to protect the brain against ischemic injury.182–188 Use of hypothermia during craniotomy for the treatment of ruptured cerebral aneurysm was evaluated in a multicenter randomized, controlled trial. The study showed that hypothermia was relatively safe but was not associated with a beneficial effect in mortality or neurological outcome among patients with good-grade aSAH.189 In addition, intraoperative hypothermia had no beneficial effect on neuropsychological function after SAH.190 Of note, the power of these 2 studies was not sufficient to detect more modest benefits from hypothermia, and there were some trends in favor of hypothermia for secondary end points.

Temporary clipping is frequently used to improve surgical conditions and prevent intraoperative rupture during the surgical dissection of aneurysms. In a retrospective study, outcome was not affected by temporary vascular occlusion.191 Induced hypertension can be considered when the duration of temporary clipping is expected to be >120 seconds, but the value of this strategy has not been well studied in aneurysm surgery. In selected patients with giant aneurysms, deep hypothermia with circulatory arrest under cardiopulmonary extracorporeal circulation has been shown to be a feasible and possibly useful technique, but outcome data are lacking.192–196 Transient cardiac pause induced by adenosine has been used to control bleeding from intraoperative aneurysm rupture or to decompact large aneurysms and facilitate aneurysm clip application197,198; however, controlled studies are needed to validate this intervention.

There is little information in the literature about anesthetic management of patients undergoing endovascular treatment of ruptured cerebral aneurysms.199–201 Generally, the anesthetic principles that apply to open surgical treatment of ruptured cerebral aneurysms also apply to endovascular treatment. The choice of anesthetic technique varies depending on the institution, with the most common techniques being conscious sedation and general anesthesia.202–204 There have been no studies comparing these 2 techniques. One of the main goals of the anesthetic technique is keeping the patient motionless to optimize the quality of the images used to perform the endovascular procedure; hence, general anesthesia with endotracheal intubation is often preferred for these procedures.

Intraprocedural aneurysm rupture during endovascular treatment presents a major challenge unlike that encountered with open craniotomy. There may be a sudden and massive rise in blood pressure with or without bradycardia attributable to an elevation in intracranial pressure. Hyperventilation and osmotic diuresis may be required to control the intracranial hypertension. Aggressive treatment of surges in blood pressure may induce ischemia; therefore, antihypertensive therapy should be reserved for patients with extreme elevations in blood pressure.

Endovascular procedures differ from open procedures in that anticoagulation with heparin is frequently administered during the embolization of aneurysms. Patients who have undergone anticoagulation require rapid reversal with protamine if intraprocedural aneurysm rupture occurs. With the increasing use of intravascular stents, the administration of antiplatelet agents (aspirin, clopidogrel, and glycoprotein IIb/IIIa receptor antagonists) during these procedures has become more common. In case of intraprocedural rupture, rapid reversal of antiplatelet activity can be attempted by platelet transfusion.

Anesthetic Management During Surgical and Endovascular Treatment: Recommendations

1. Minimization of the degree and duration of intraoperative hypotension during aneurysm surgery is probably indicated (Class IIa; Level of Evidence B).
2. There are insufficient data on pharmacological strategies and induced hypertension during temporary vessel occlusion to make specific recommendations, but there are instances when their use may be considered reasonable (Class IIb; Level of Evidence C).
3. Induced hypothermia during aneurysm surgery is not routinely recommended but may be a reasonable option in selected cases (Class III; Level of Evidence B).
4. Prevention of intraoperative hyperglycemia during aneurysm surgery is probably indicated (Class IIa; Level of Evidence B).
5. The use of general anesthesia during endovascular treatment of ruptured cerebral aneurysms can be beneficial in selected patients (Class IIa; Level of Evidence C).

Management of Cerebral Vasospasm and DCI After aSAH

Narrowing (vasospasm) of the angiographically visible cerebral arteries after aSAH is common, occurring most frequently 7 to 10 days after aneurysm rupture and resolving spontaneously after 21 days. The cascade of events culminating in arterial narrowing is initiated when oxyhemoglobin comes in contact with the abluminal side of the vessel.205 The pathways leading to arterial narrowing have been the focus of extensive basic research, but no effective preventive therapy has been developed to date. Part of the reason for this lack of success likely stems from the fact that vasospasm occurs at multiple levels in the arterial and arteriolar circulation. Large artery narrowing seen in angiographically visible vessels only results in ischemic neurological symptoms in 50% of cases, and although there is a correlation between the severity of large artery spasm and symptomatic ischemia, there are patients with severe large artery spasm who never become symptomatic and others with quite modest spasm who not only develop symptoms but go on to develop infarction.206 Probably many factors contribute to the development of ischemia and infarction, including but not limited to distal microcirculatory failure, poor collateral anatomy, and genetic or physiological variations in cellular ischemic tolerance.207,208

DCI, especially that associated with arterial vasospasm, remains a major cause of death and disability in patients with aSAH. The management of aSAH-induced vasospasm is complex. Many significant advances in the understanding of aSAH-induced vasospasm and DCI have been made since
publication of the previous version of these guidelines, which focused on prevention with oral nimodipine and maintenance of euвolemia, as well as treatment with triple-H therapy (hemodynamic augmentation therapy) and/or endovascular therapy with vasodilators and angioplasty balloons. First, the case for nimodipine is even stronger, with a recent comprehensive meta-analysis confirming improved neurological outcomes by preventing processes other than large-vessel narrowing.209,210 Although there have been sparse new important data on the lack of benefit for prophylactic hypertension compared with maintenance of euвolemia, new data show that both prophylactic angioplasty of the basilar cerebral arteries and antiplatelet prophylaxis are ineffective in reducing morbidity.211–213 Similarly, the only supportive data for the use of lumbar drainage come from a single case-control study,214 although there is ongoing investigation on the value of the use of lumbar drainage come from a single case-control study,214 although there is ongoing investigation on the value of low flow velocity by transcranial Doppler, for which the data are best for the middle cerebral artery territory.224–226 Perfusion CT is a promising technology, although repeat measurements are limited by the risks of dye load and radiation exposure.226

When DCI is diagnosed, the initial treatment is the induction of hemodynamic augmentation to improve cerebral perfusion. No randomized trials of this intervention have been performed, but the rapid improvement of many patients with this therapy and their worsening when it is stopped prematurely are convincing proof of efficacy. The exact mechanism of benefit is unclear. In some patients, increased mean arterial pressures may increase cerebral blood flow in the setting of autoregulatory dysfunction. In others, there may be some direct transmural pressure effect that leads to arterial dilatation.227 Traditionally, hemodynamic augmentation has consisted of hemodilution (a common occurrence in this population), hypervolemia, and hypertensive therapy. Accumulating literature has shifted the focus from this triple-H therapy to the maintenance of euвolemia and induced hypertension.228

One novel method of hemodynamic augmentation under investigation is an aortic balloon device, approved under a humanitarian device exemption.229 Endovascular intervention is often used in patients who do not improve with hemodynamic augmentation and those with sudden focal neurological deficits and focal lesions on angiography referable to their symptoms.230 Interventions generally consist of balloon angioplasty for accessible lesions and vasodilator infusion for more distal vessels. Many different vasodilators are in use. In general, these are calcium channel blockers, but nitric oxide donors have been used in small series as well.231 Papaverine is used less frequently because it can produce neurotoxicity.232 The primary limitation of vasodilator therapy is the short duration of benefit. As with hemodynamic augmentation, there have been no randomized trials of these interventions, but large case series have demonstrated angiographic and clinical improvement.233

Management of Cerebral Vasospasm and DCI

After aSAH: Recommendations

1. Oral nimodipine should be administered to all patients with aSAH (Class I; Level of Evidence A). (It should be noted that this agent has been shown to improve neurological outcomes but not cerebral vasospasm. The value of other calcium antagonists, whether administered orally or intravenously, remains uncertain.)

2. Maintenance of euвolemia and normal circulating blood volume is recommended to prevent DCI (Class
Management of Hydrocephalus Associated With aSAH

Acute hydrocephalus occurs in 15% to 87% of patients with aSAH.334–340 Chronic shunt-dependent hydrocephalus, on the other hand, occurs in 8.9% to 48% of patients with aSAH.334–338,340–344 There is only 1 randomized, controlled trial pertaining to the management of hydrocephalus associated with aSAH245 and 2 meta-analyses236,241; the rest of the literature consists of nonrandomized case-control, case series, or case reports. Acute hydrocephalus associated with aSAH is usually managed by external ventricular drainage (EVD) or lumbar drainage. EVD for patients with aSAH-associated hydrocephalus is generally associated with neurological improvement.246–249 The risk of aneurysm rebleeding with EVD has been studied in 3 retrospective case series, 1 of which found a higher risk of rebleeding with EVD,249 whereas the other 2 studies found no increased risk.239,251

Lumbar drainage for the treatment of aSAH-associated hydrocephalus has been reported to be safe (no increase in the risk of rebleeding), but it has only been examined in retrospective series,214,252–255 1 of which specifically evaluated intraoperative lumbar drainage for brain relaxation.256 The theoretical risk of tissue shift after placement of a lumbar drain in patients with severe intracranial hypertension should be considered when deciding what method of cerebrospinal fluid diversion to use, particularly in patients with associated intraparenchymal hematomas. When obstructive hydrocephalus is suspected, an EVD should be preferred. Preliminary data have suggested that lumbar drainage is associated with reduced incidence of vasospasm.214,255 Serial lumbar punctures to manage acute aSAH-associated hydrocephalus have been described as safe, but this strategy has only been assessed in small retrospective series.239,257

Chronic hydrocephalus associated with aSAH is usually treated with ventricular shunt placement. Only a proportion of patients with aSAH-associated acute hydrocephalus develop shunt-dependent chronic hydrocephalus. The method of determining which patients require ventricular shunt placement was studied in a single-center, prospective, randomized, controlled trial in which 41 patients were randomized to rapid weaning of EVD (wean period <24 hours) and 40 patients were randomized to gradual EVD weaning (wean period 96 hours).245 There was no difference in the rate of shunt placement (63.4% rapid versus 62.5% gradual), but the gradual wean group had 2.8 more days in the intensive care unit (P=0.0002) and 2.4 more days in the hospital (P=0.0314).245

A number of retrospective series have attempted to identify factors predictive of aSAH-associated shunt-dependent chronic hydrocephalus.235,236,240,242 A meta-analysis336 of 5 nonrandomized studies236,258–261 with 1718 pooled patients (1336 who underwent clipping, 382 who underwent coiling) found a lower risk of shunt dependency in the clipping group (relative risk, 0.74; 95% confidence interval, 0.58–0.94) than in the coiling group (P=0.01); however, only 1 of the 5 studies showed an independent significant difference.258 Three other nonrandomized series not included in the meta-analysis showed no significant difference between clipping and coiling in shunt-dependent chronic hydrocephalus.237,244,262 Fenestration of the lamina terminalis has been suggested to reduce the incidence of shunt-dependent chronic hydrocephalus, yet a meta-analysis243 of 11 nonrandomized studies234,260,263–271 pooled 1973 patients (975 who had undergone fenestration and 998 who had not) and found no significant difference in shunt-dependent hydrocephalus between patients who had undergone fenestration of the lamina terminalis and those who had not (10% in the fenestrated cohort versus 14% in the nonfenestrated cohort; P=0.09). A nonrandomized study not included in the meta-analysis compared 95 patients who underwent aneurysm clipping, cisternal blood evacuation, and lamina terminalis fenestration with 28 comparable, non–blood-cleansed, endovascular therapy–treated patients and found that shunt-dependent hydrocephalus occurred in 17% of surgical patients versus 33% of patients treated with endovascular therapy (statistical significance not reported).237

Management of Hydrocephalus Associated With aSAH: Recommendations

1. aSAH-associated acute symptomatic hydrocephalus should be managed by cerebrospinal fluid diversion (EVD or lumbar drainage, depending on the clinical scenario) (Class I; Level of Evidence B). (Revised recommendation from previous guidelines)
2. aSAH-associated chronic symptomatic hydrocephalus should be treated with permanent cerebrospinal fluid diversion (Class I; Level of Evidence C). (Revised recommendation from previous guidelines)
3. Weaning EVD over >24 hours does not appear to be effective in reducing the need for ventricular shunting (Class III; Level of Evidence B). (New recommendation)
4. Routine fenestration of the lamina terminalis is not useful for reducing the rate of shunt-dependent hydrocephalus and therefore should not be routinely
performed. (Class III; Level of Evidence B). (New recommendation)

Management of Seizures Associated With aSAH

The incidence, future implications, and management of seizures associated with aSAH are controversial. At present, no randomized, controlled trials are available to guide decisions on prophylaxis or treatment of seizures.\(^2,272\) A relatively high percentage of aSAH patients (as many as 26\%) experience seizure-like episodes,\(^99,272,273\) but it remains unclear whether these episodes are verifiably epileptic in origin.\(^99,274\) More recent retrospective reviews suggest a lower seizure incidence of 6\% to 18\%,\(^275–278\) and 2 of these studies\(^276,278\) found that the majority of such patients reported onset of seizure occurring before medical evaluation. Delayed seizures occurred in 3\% to 7\% of patients.\(^276,278\) Retrospective studies have identified several risk factors for the development of early seizures associated with aSAH, including aneurysm in the middle cerebral artery,\(^279\) thickness of aSAH clot,\(^276,278\) associated intracerebral hematoma,\(^280–282\) rebleeding,\(^276\) infarction,\(^283\) poor neurological grade,\(^276\) and history of hypertension.\(^98\)

The mode of treatment for patients with ruptured aneurysms also appears to influence the subsequent development of seizures. One study of patients treated by endovascular means reported no periprocedural seizures and a delayed seizure rate of 3\%.\(^284\) Moreover, extended follow-up of patients enrolled in the ISAT demonstrated a significantly lower incidence of seizures in patients treated with endovascular coiling.\(^140\) The association between seizures and functional outcome remains unclear. Some studies have reported no impact on outcome,\(^276,278\) whereas others found seizures to be independently associated with worse outcome.\(^275\) Two recent large, retrospective, single-institution studies of patients with aSAH found that nonconvulsive status epilepticus is a very strong predictor of a poor outcome.\(^285,286\) Although high-quality evidence for routine anticonvulsant use in aSAH is lacking, short-term prophylactic antiepileptic therapy is still commonly used in patients with aSAH.\(^274,276,278\) Based on the argument that seizures in acutely ill patients with aSAH could lead to additional injury or rebleeding from an unsecured aneurysm. Evidence from a few relatively small non-randomized studies of craniotomy patients supports this position,\(^281,282,287\) but the efficacy of routine use of anticonvulsants in patients with aSAH managed with microsurgical techniques remains unproven.\(^288–290\)

Any purported benefit of routine anticonvulsant use in aSAH must be tempered by a consideration of the potential risks of such use. In 1 large single-institution study in which anticonvulsants were used routinely, adverse drug effects were seen in 23\% of patients.\(^276\) Another single-center retrospective study found that the use of prophylactic phenytoin was independently associated with a worse cognitive outcome at 3 months after aSAH.\(^291\) Data pooled from trials of the impact of other therapies also suggest a worse outcome in those treated with anticonvulsants, but use of anticonvulsants was also associated with vasospasm, DCI, and fever, which suggests that there may have been bias in who was treated with antiepileptic drugs.\(^292\) Although retrospective studies have not demonstrated a benefit for use of prophylactic anticonvulsants after aSAH,\(^273,288\) the studies were small and hampered by limitations (eg, anticonvulsant levels were not routinely monitored).\(^2,273,288\)

Management of Seizures Associated With aSAH: Recommendations

1. The use of prophylactic anticonvulsants may be considered in the immediate posthemorrhagic period (Class IIb; Level of Evidence B).

2. The routine long-term use of anticonvulsants is not recommended (Class III; Level of Evidence B) but may be considered for patients with known risk factors for delayed seizure disorder, such as prior seizure, intracerebral hematoma, intractable hypertension, infarction, or aneurysm at the middle cerebral artery (Class IIb; Level of Evidence B).

Management of Medical Complications Associated With aSAH

Both hypernatremia and hyponatremia are frequently observed in the acute phase after aSAH.\(^293,294\) The reported incidence of hyponatremia in this disease ranges from 10\% to 30\%. Hypernatremia has been chronologically associated with the onset of sonographic and clinical vasospasm.\(^295,296\) Hyponatremia can develop from different mechanisms after aSAH. The syndrome cerebral salt wasting is produced by excessive secretion of natriuretic peptides and causes hypotension from excessive natriuresis, which may also provoke volume contraction.\(^297\) The diagnosis of cerebral salt wasting is more common in patients with poor clinical grade, ruptured anterior communicating artery aneurysms, and hydrocephalus, and it may be an independent risk factor for poor outcome.\(^298–300\) Uncontrolled studies using crystalloid or colloid agents suggest that aggressive volume resuscitation can ameliorate the effect of cerebral salt wasting on the risk of cerebral ischemia after aSAH.\(^301,302\) One retrospective study has suggested that 3\% saline solution is effective in correcting hyponatremia in this setting.\(^303\) In addition, use of hypertonic saline solution appears to increase regional cerebral blood flow, brain tissue oxygen, and pH in patients with high-grade aSAH.\(^304\)

Two randomized, controlled trials have been performed to evaluate fludrocortisones to correct hyponatremia and fluid balance. One trial found that it helped to correct the negative sodium balance, and the other reported a reduced need for fluids and improved sodium levels using this mineralocorticoid.\(^305,306\) A similar randomized, placebo-controlled trial showed reduced natriuresis and a lower rate of hyponatremia in aSAH patients treated with hydrocortisone.\(^307\) The value of albumin as an efficient volume expander during the vasospasm phase in aSAH has been suggested in uncontrolled studies, but there is no clear evidence of its superiority over crystalloids in patients with aSAH.\(^308\)

Fever is the most common medical complication in aSAH.\(^309\) The presence of fever of noninfectious (central) origin has been associated with severity of injury, amount of hemorrhage, and development of vasospasm, and it may represent a marker of a systemic inflammatory state triggered...
by blood and its byproducts. Analysis of data from a prospectively collected registry of aSAH indicated that fever was independently associated with worse cognitive outcome in survivors of aSAH. Improved functional outcome with effective control of fever has been reported.

Both animal studies and human case series have demonstrated an association between elevated blood glucose concentration and poor outcome after ischemic brain injury. The mechanisms explaining such an association in human beings are unclear. Data obtained from consecutive patients with aSAH using historical controls to compare aggressive versus standard management of hyperglycemia suggest that effective glucose control after aSAH can significantly reduce the risk of poor outcome in these patients. Nevertheless, even serum glucose levels within the normal range may be associated with brain energy metabolic crisis and lactate-pyruvate ratio elevation in patients with poor-grade aSAH.

Anemia is common after aSAH and may compromise brain oxygen delivery. Transfusion of red blood cells in anemic patients with aSAH results in a significant rise in cerebral oxygen delivery and a reduction in oxygen extraction ratio. Data obtained from prospective registries of patients with aSAH suggest that higher hemoglobin values are associated with improved outcomes after aSAH. Nevertheless, thresholds for blood transfusion have been dictated in a nonsystematic manner and have therefore varied widely. Furthermore, red blood cell transfusions, as used in daily practice, have been associated with worse outcomes in aSAH in some series. Recently, a prospective randomized trial has shown the safety and feasibility of keeping a higher hemoglobin goal in patients with aSAH who are at high risk of vasospasm. The optimal hemoglobin goal after aSAH is not yet known, however.

Two additional medical complications are heparin-induced thrombocytopenia and deep venous thrombosis. With regard to the former, the incidence, based on 3 single-center series, is likely ≈5% and does not appear to be related to the use of heparin for deep venous thrombosis prophylaxis, but rather to the number of angiographic procedures performed. Patients with heparin-induced thrombocytopenia type II appear to have higher rates of thrombotic complications and symptomatic vasospasm/DCI, more deaths, and significantly less favorable outcomes. It is currently unclear whether there is a practical means of preventing heparin-induced thrombocytopenia, given the need for heparin in many angiographic procedures, but it is clearly important to recognize this complication to avoid further heparin exposure and to use instead a nonheparin alternative under the guidance of a hematologist. By comparison, deep venous thrombosis has long been recognized as a relatively frequent occurrence after aSAH, especially in patients immobilized because of poor mental status. Nevertheless, in examining cohorts in which routine prophylaxis (subcutaneous heparinoids and external pneumatic compression sleeves) was used, recent data suggest that although screening protocols may identify additional cases of asymptomatic thrombosis, there is no significant difference in the incidence of pulmonary embolism between those screened and those not screened.

Management of Medical Complications Associated With aSAH: Recommendations

1. Administration of large volumes of hypotonic fluids and intravascular volume contraction is not recommended after aSAH (Class III; Level of Evidence B).
2. Monitoring volume status in certain patients with recent aSAH by some combination of central venous pressure, pulmonary wedge pressure, and fluid balance is reasonable, as is treatment of volume contraction with crystalloid or colloid fluids (Class IIa; Level of Evidence B).
3. Aggressive control of fever to a target of normothermia by use of standard or advanced temperature modulating systems is reasonable in the acute phase of aSAH (Class IIa; Level of Evidence B). (New recommendation)
4. Careful glucose management with strict avoidance of hypoglycemia may be considered as part of the general critical care management of patients with aSAH (Class IIb; Level of Evidence B).
5. The use of packed red blood cell transfusion to treat anemia might be reasonable in patients with aSAH who are at risk of cerebral ischemia. The optimal hemoglobin goal is still to be determined (Class IIb; Level of Evidence B). (New recommendation)
6. The use of fludrocortisone acetate and hypertonic saline solution is reasonable for preventing and correcting hyponatremia (Class IIa; Level of Evidence B).
7. Heparin-induced thrombocytopenia and deep venous thrombosis are relatively frequent complications after aSAH. Early identification and targeted treatment are recommended, but further research is needed to identify the ideal screening paradigms (Class I; Level of Evidence B). (New recommendation)

Summary and Conclusions

The management of aSAH is a complex undertaking, and the current state of knowledge is in rapid evolution. This update, which is based on a mere 42 months of publications, identified 22 new recommendations (Table 4), 5 of which were Class I recommendations. There were also 9 changes in prior recommendations. In total, there are now 22 Class I recommendations (Table 3). Although these data show that frequent revision of these guidelines is clearly needed, the data presented here only begin to scratch the surface of the burgeoning knowledge in this fast-developing field. Those faced with managing these patients will thus do well to use these guidelines as merely the starting point for doing everything possible to improve the outcomes of patients with aSAH.

This table represents the relationships of writing group members that may be perceived as actual or reasonably perceived conflicts of interest as reported on the Disclosure Questionnaire, which all writing group members are required to complete and submit. A relationship is considered to be “significant” if (1) the person receives $10,000 or more during any 12-month period, or 5% or more of the person’s gross income; or (2) the person owns 5% or more of the voting stock or share of the entity, or owns $10,000 or more of the fair market value of the entity. A relationship is considered to be “modest” if it is less than “significant” under the preceding definition.

*Modest.

Executive Summary: Guidelines for the Management of Aneurysmal Subarachnoid Hemorrhage

A Guideline for Healthcare Professionals From the American Heart Association/American Stroke Association

The American Academy of Neurology affirms the value of this statement as an educational tool for neurologists.

Endorsed by the American Association of Neurological Surgeons and Congress of Neurological Surgeons; and by the Society of NeuroInterventional Surgery

E. Sander Connolly, Jr, MD, FAHA, Chair; Alejandro A. Rabinstein, MD, Vice Chair; J. Ricardo Carhuapoma, MD, FAHA; Colin P. Derdeyn, MD, FAHA; Jacques Dion, MD, FRCP; Randall T. Higashida, MD, FAHA; Brian L. Hoh, MD, FAHA; Catherine J. Kirkness, PhD, RN; Andrew M. Naidech, MD, MSPH; Christopher S. Ogilvy, MD; Aman B. Patel, MD; B. Gregory Thompson, MD; Paul Vespa, MD, FAAN; on behalf of the American Heart Association Stroke Council, Council on Cardiovascular Radiology and Intervention, Council on Cardiovascular Nursing, Council on Cardiovascular Surgery and Anesthesia, and Council on Clinical Cardiology

Aneurysmal subarachnoid hemorrhage (aSAH) is a significant cause of morbidity and mortality throughout the world. Although aggressive medical and surgical care for this disease has resulted in marked improvements in outcomes for those fortunate enough to be admitted to tertiary care centers experienced in handling this disease, many patients still die before hospitalization, and many others are treated in low-volume centers, where their medical and surgical options may be limited. Thus, although efforts continue to focus on developing better methods for treating patients with aSAH, considerable energy has been and will continue to be focused on primary and secondary prevention and systems of care.

This Executive Summary contains only the recommendations from the 2012 Guidelines for the Management of Aneurysmal Subarachnoid Hemorrhage. The previous version of the guidelines was published in 2009. The 2012 version serves to update those guidelines. As such, differences from former recommendations are specified in the present work. The writing group met by telephone to determine subcategories to evaluate. These subcategories included incidence, risk factors, prevention, natural history and outcome, diagnosis, prevention of rebleeding, management of aneurysms, systems of care, anesthetic management during repair, management of vasospasm, management of hydrocephalus, management of seizures, and management of medical complications. Each subcategory was led by 1 author, with 1 or 2 additional authors who made contributions. Full MEDLINE searches were conducted of all English-language papers on treatment of relevant human disease. Drafts of summaries and recommendations were circulated to the entire writing group for feedback. A conference call was held to discuss controversial issues. Sections were revised and merged by the writing group chair. The resulting draft was sent to the entire writing group for comment. Comments were incorporated into the draft by the writing group chair and vice chair, and the entire writing group was asked to approve the final draft. The chair and vice chair revised the document in response to peer review, and the document was again sent to the entire writing group for suggestions and approval.

The recommendations follow the American Heart Association Stroke Council’s methods of classifying the level of certainty of the treatment effect and the class of evidence (Tables 1 and 2). This Executive Summary includes all recommendations, 22 of which are new and 9 of which were revised from the prior manuscript. In total, 22 of the recommendations are categorized as Class I recommendations. Two of the Class I recommendations are based on Level A evidence, and 2 are based on Level C evidence. The remainder of the Class I recommendations are based on Level B evidence.

Recommendations

Risk Factors for and Prevention of aSAH

- Treatment of high blood pressure with antihypertensive medication is recommended to prevent
ischemic stroke, intracerebral hemorrhage, and cardiac, renal, and other end-organ injury (Class I; Level of Evidence A).

- Hypertension should be treated, and such treatment may reduce the risk of aSAH (Class I; Level of Evidence A).

- Tobacco use and alcohol misuse should be avoided to reduce the risk of aSAH (Class I; Level of Evidence A).

- In addition to the size and location of the aneurysm and the patient’s age and health status, it might be reasonable to consider morphological and hemodynamic characteristics of the aneurysm when discuss-

ing the risk of aneurysm rupture (Class IIb; Level of Evidence B). (New recommendation)

- Consumption of a diet rich in vegetables may lower the risk of aSAH (Class IIb; Level of Evidence B). (New recommendation)

- It may be reasonable to offer noninvasive screening to patients with familial (at least 1 first-degree relative) aSAH and/or a history of aSAH to evaluate for de novo aneurysms or late regrowth of a treated aneurysm, but the risks and benefits of this screening require further study (Class IIb; Level of Evidence B).
After any aneurysm repair, immediate cerebrovascular imaging is generally recommended to identify remnants or recurrence of the aneurysm that may require treatment (Class I; Level of Evidence B). (New recommendation)

Natural History and Outcome of aSAH

- The initial clinical severity of aSAH should be determined rapidly by use of simple validated scales (eg, Hunt and Hess, World Federation of Neurological Surgeons), because it is the most useful indicator of outcome after aSAH (Class I; Level of Evidence B).
- The risk of early aneurysm rebleeding is high, and rebleeding is associated with very poor outcomes. Therefore, urgent evaluation and treatment of patients with suspected aSAH is recommended (Class I; Level of Evidence B).
- After discharge, it is reasonable to refer patients with aSAH for a comprehensive evaluation, including cognitive, behavioral, and psychosocial assessments (Class IIa; Level of Evidence B). (New recommendation)

Clinical Manifestations and Diagnosis of aSAH

- aSAH is a medical emergency that is frequently misdiagnosed. A high level of suspicion for aSAH should exist in patients with acute onset of severe headache (Class I; Level of Evidence B).
- Acute diagnostic workup should include noncontrast head computed tomography, which, if nondiagnostic, should be followed by lumbar puncture (Class I; Level of Evidence B).
- Computed tomographic angiography may be considered in the workup of aSAH. If an aneurysm is detected by computed tomographic angiography, this study may help guide the decision for type of aneurysm repair, but if computed tomographic angiography is inconclusive, digital subtraction angiography is still recommended (except possibly in the instance of classic perimesencephalic aSAH) (Class IIb; Level of Evidence C). (New recommendation)
- Magnetic resonance imaging, fluid-attenuated inversion recovery, proton density, diffusion-weighted imaging, and gradient echo sequences may be reasonable for the diagnosis of aSAH in patients with a nondiagnostic computed tomographic scan, although a negative result does not obviate the need for cerebrospinal fluid analysis (Class IIb; Level of Evidence C). (New recommendation)
- Digital subtraction angiography with 3-dimensional rotational angiography is indicated for detection of aneurysm in patients with aSAH (except when the aneurysm was previously diagnosed by a noninvasive angiogram) and for planning treatment (to determine whether an aneurysm is amenable to coiling or to expedite microsurgery) (Class I; Level of Evidence B). (New recommendation)

Medical Measures to Prevent Rebleeding After aSAH

- Between the time of aSAH symptom onset and aneurysm obliteration, blood pressure should be controlled with a titratable agent to balance the risk of stroke, hypertension-related rebleeding, and maintenance of cerebral perfusion pressure (Class I; Level of Evidence B). (New recommendation)
- The magnitude of blood pressure control to reduce the risk of rebleeding has not been established, but a decrease in systolic blood pressure to <160 mm Hg is reasonable (Class IIa; Level of Evidence C). (New recommendation)
- For patients with an unavoidable delay in obliteration of aneurysm, a significant risk of rebleeding, and no compelling medical contraindications, short-term (<72 hours) therapy with tranexamic acid or aminocaproic acid is reasonable to reduce the risk of early aneurysm rebleeding (Class IIa; Level of Evidence B). (Revised recommendation from previous guidelines)
Surgical and Endovascular Methods of Treatment of Ruptured Cerebral Aneurysms

- Surgical clipping or endovascular coiling of the ruptured aneurysm should be performed as early as feasible in the majority of patients to reduce the rate of rebleeding after aSAH (Class I; Level of Evidence B).
- Complete obliteration of the aneurysm is recommended whenever possible (Class I; Level of Evidence B).
- Determination of aneurysm treatment, as judged by both experienced cerebrovascular surgeons and endovascular specialists, should be a multidisciplinary decision based on characteristics of the patient and the aneurysm (Class I; Level of Evidence C). (Revised recommendation from previous guidelines)
- For patients with ruptured aneurysms judged to be technically amenable to both endovascular coiling and neurosurgical clipping, endovascular coiling should be considered (Class I; Level of Evidence B). (Revised recommendation from previous guidelines)
- In the absence of a compelling contraindication, patients who undergo coiling or clipping of a ruptured aneurysm should have delayed follow-up vascular imaging (timing and modality to be individualized), and strong consideration should be given to retreatment, either by repeat coiling or microsurgical clipping, if there is a clinically significant (eg, growing) remnant (Class I; Level of Evidence B). (New recommendation)
- Microsurgical clipping may receive increased consideration in patients presenting with large (>50 mL) intraparenchymal hematomas and middle cerebral artery aneurysms. Endovascular coiling may receive increased consideration in the elderly (>70 years of age), in those presenting with poor-grade (World Federation of Neurological Surgeons classification IV/V) aSAH, and in those with aneurysms of the basilar apex (Class IIb; Level of Evidence C). (New recommendation)
- Stenting of a ruptured aneurysm is associated with increased morbidity and mortality, and should only be considered when less risky options have been excluded (Class III; Level of Evidence C). (New recommendation)

Hospital Characteristics and Systems of Care

- Low-volume hospitals (eg, <10 aSAH cases per year) should consider early transfer of patients with aSAH to high-volume centers (eg, >35 aSAH cases per year) with experienced cerebrovascular surgeons, endovascular specialists, and multidisciplinary neuro-intensive care services (Class I; Level of Evidence B). (Revised recommendation from previous guidelines)
- Annual monitoring of complication rates for surgical and interventional procedures is reasonable (Class IIa; Level of Evidence C). (New recommendation)
- A hospital credentialing process to ensure that proper training standards have been met by individual physicians treating brain aneurysms is reasonable (Class IIa; Level of Evidence C). (New recommendation)

Anesthetic Management During Surgical and Endovascular Treatment

- Minimization of the degree and duration of intraoperative hypotension during aneurysm surgery is probably indicated (Class IIa; Level of Evidence B).
- There are insufficient data on pharmacological strategies and induced hypertension during temporary vessel occlusion to make specific recommendations, but there are instances when their use may be considered reasonable (Class IIb; Level of Evidence C).
- Induced hypothermia during aneurysm surgery is not routinely recommended but may be a reasonable option in selected cases (Class III; Level of Evidence B).
- Prevention of intraoperative hyperglycemia during aneurysm surgery is probably indicated (Class IIa; Level of Evidence B).
- The use of general anesthesia during endovascular treatment of ruptured cerebral aneurysms can be beneficial in selected patients (Class IIa; Level of Evidence C).

Management of Cerebral Vasospasm and Delayed Cerebral Ischemia After aSAH

- Oral nimodipine should be administered to all patients with aSAH (Class I; Level of Evidence A). (It should be noted that this agent has been shown to improve neurological outcomes but not cerebral vasospasm. The value of other calcium antagonists, whether administered orally or intravenously, remains uncertain.)
- Maintenance of euvolemia and normal circulating blood volume is recommended to prevent delayed cerebral ischemia (Class I; Level of Evidence B). (Revised recommendation from previous guidelines)
- Prophylactic hypervolemia or balloon angioplasty before the development of angiographic spasm is not recommended (Class III; Level of Evidence B). (New recommendation)
- Transcranial Doppler is reasonable to monitor for the development of arterial vasospasm (Class IIa; Level of Evidence B). (New recommendation)
- Perfusion imaging with computed tomography or magnetic resonance can be useful to identify regions of potential brain ischemia (Class IIa; Level of Evidence B). (New recommendation)
- Induction of hypertension is recommended for patients with delayed cerebral ischemia unless blood pressure is elevated at baseline or cardiac status precludes it (Class I; Level of Evidence B). (Revised recommendation from previous guidelines)
Cerebral angioplasty and/or selective intra-arterial vasodilator therapy is reasonable in patients with symptomatic cerebral vasospasm, particularly those who are not rapidly responding to hypertensive therapy (Class IIa; Level of Evidence B). (Revised recommendation from previous guidelines)

Management of Hydrocephalus Associated With aSAH

- aSAH-associated acute symptomatic hydrocephalus should be managed by cerebrospinal fluid diversion (external ventricular drainage or lumbar drainage, depending on the clinical scenario) (Class I; Level of Evidence B). (Revised recommendation from previous guidelines)
- aSAH-associated chronic symptomatic hydrocephalus should be treated with permanent cerebrospinal fluid diversion (Class I; Level of Evidence C). (Revised recommendation from previous guidelines)
- Weaning external ventricular drainage over \( \geq 24 \) hours does not appear to be effective in reducing the need for ventricular shunting (Class III; Level of Evidence B). (New recommendation)
- Routine fenestration of the lamina terminalis is not useful for reducing the rate of shunt-dependent hydrocephalus and therefore should not be routinely performed (Class III; Level of Evidence B). (New recommendation)

Management of Seizures Associated With aSAH

- The use of prophylactic anticonvulsants may be considered in the immediate posthemorrhagic period (Class IIb; Level of Evidence B).
- The routine long-term use of anticonvulsants is not recommended (Class III; Level of Evidence B) but may be considered for patients with known risk factors for delayed seizure disorder, such as prior seizure, intracerebral hematoma, intractable hypertension, infarction, or aneurysm at the middle cerebral artery (Class IIb; Level of Evidence B).

Management of Medical Complications Associated With aSAH

- Administration of large volumes of hypotonic fluids and intravascular volume contraction is not recommended after aSAH (Class III; Level of Evidence B).
- Monitoring volume status in certain patients with recent aSAH by use of standard or advanced temperature modulating systems is reasonable in the acute phase of aSAH (Class IIa; Level of Evidence B).
- Aggressive control of fever to a target of normothermia by use of standard or advanced temperature modulation systems is reasonable in the acute phase of aSAH (Class IIa; Level of Evidence B). (New recommendation)
- Careful glucose management with strict avoidance of hypoglycemia may be considered as part of the general critical care management of patients with aSAH (Class IIb; Level of Evidence B).
- The use of packed red blood cell transfusion to treat anemia might be reasonable in patients with aSAH who are at risk of cerebral ischemia. The optimal hemoglobin goal is still to be determined (Class IIb; Level of Evidence B). (New recommendation)
- The use of fludrocortisone acetate and hypertonic saline solution is reasonable for preventing and correcting hyponatremia (Class IIa; Level of Evidence B).
- Heparin-induced thrombocytopenia and deep venous thrombosis are relatively frequent complications after aSAH. Early identification and targeted treatment are recommended, but further research is needed to identify the ideal screening paradigms (Class I; Level of Evidence B). (New recommendation)

References

References are available in the full text of this guideline: http://stroke.ahajournals.org/lookup/doi/10.1161/STR.0b013e3182587839.

1. aSAHの発症率と罹病率
これまでもaSAHの発症率に地域差があることが報告来ていたが、近年のレビューでもaSAHの発症率がフィンランドと日本で高く、中米・南米で低いことが示され、世界的には人口10万人につき年間2〜16例と推定されている。

2. aSAHの危険因子と予防（表2）
高血圧、喫煙、過度の飲酒、交感神経作用薬（コカインなど）はaSAHの危険因子であるが、未破裂脳動脈瘤、aSAHの既往、脳動脈瘤の家族歴、家族性多嚢胞性腎やIV型Ehlers-Danlos症候群などもaSAHのリスクを増加させる。予防としてaSAH患者の第一度近親者をスクリーニングすることが妥当かもしれない。また野菜が豊富な食事によりaSAHのリスクが低下することが報告されている。

3. aSAHの自然経過と転帰（表3）
aSAHの死亡率（中央値）は米国32%、欧州43%、日本27%と報告されている。脳動脈瘤の疾患の調査は少ないが、脳動脈瘤の疾患の治療の研究は進んでいる。脳動脈瘤は未破裂脳動脈瘤、破裂脳動脈瘤、塞性脳動脈瘤などがある。脳動脈瘤の治療は手術、放射線療法、薬物療法などがある。脳動脈瘤の治療の適応は症例により異なる。脳動脈瘤の治療の適応は症例により異なる。

4. aSAHの臨床徵候と診断（表4）
aSAHの頭痛は突発性で瞬時にピークに達する激痛（thunderclap headache:雷鳴頭痛）が特徴である。aSAHの前に、より軽度の警告頭痛（sentinel headache）が10〜43%に起こる。頭部単純CTはaSAH診断の要であり、発症後3日以内には感度は100%に近いが、発症5〜7日後には脳脊髄液検査の必要が生じる。磁気共鳴画像法（MRI）は頭部CTが陰性の症例でaSAHの診断をつけることを可能にしている。CT血管造影は3mm以下の動脈瘤検出に問題があるとされ、動脈瘤のない脳動脈瘤SAHにおいてはデジタルサブトラクション血管造影（DSA）の必要性について議論が続く。脳動脈瘤がクリッピング術で治療される場合にはCTAの単独検査で十分なこともあるが、CTAだけで血管内治療の適応を判定することに議論がある。三次元と二次元血管造影の併用は、空間分解能の高い動脈瘤の描出に最適である。

5. aSAH後の再出血を防ぐための内科的処置（表5）
脳動脈瘤の再出血率は高い死亡率を伴う。早期に動脈瘤の再出血を防ぐための治療が必要である。aSAH後の急性期高血圧は動脈瘤が閉塞されるまでコントロールされるべきであるが、血圧管理の詳細は決められていない。用量調節が可能な薬物としてはニカルジピン、ラベタロール、ニトロプロシドがある。動脈瘤閉塞が遅延する場合、短期の抗線維素溶解療法が再出血のリスクを低減させる効果がある。
脳動脈瘤によるくも膜下出血の管理に関するガイドライン

6. 破裂脳動脈瘤の脳外科的治療と血管内治療（表6）
ISAT試験では2,143例で開頭クリッピング術と血管内コイル塞栓術が無作為試験で比較されたが、1年後の死亡率で開頭クリッピング群が高かった（31%対24%）。遅発性再出血はコイル群で高く（2.9%対0.9%）、脳動脈瘤の完全閉塞はクリッピング群で高かった（81%対58%）。血管内コイル塞栓術の短期効果は確立されているが、持続性について懸念があるため、長期間に経過観察を続ける必要がある。血管内治療と顕微鏡下手術の選択については、中大脳動脈瘤はクリッピング術よりコイル塞栓術が良いことが示唆されている。大きな脳実質内血腫（>50mL）を伴う症例には、血腫除去が可能であることから、顕微鏡下手術が好まれる。血管攣縮を発症した症例には血管内治療が選ばれる。臨床的グレードの悪い症例、特に老齢患者では、開頭クリッピング術を考慮すべきである。脳底動脈瘤に対しては、クリッピング術に比して死亡率と合併症が低いことから、血管内治療が広く受け入れられている。

7. 病院の特徴と診療体制（表7）
脳動脈瘤クリッピング術を受けた患者では、教育病院や大規模病院において良好な転帰と低い死亡率が得られ、血管内治療でも同様の結果が示されている。aSAH症例数と血管内治療および神経系集中治療室の存在が良好な転帰の重要な決定因子であると考えられている。米国では脳血管系の血管内治療教育プログラムの認定制度と総合脳卒中センターの制定により、aSAHの管理の均等化が得られる。総合脳卒中センターに重要な条件としては、血管内治療以外に、熟練した血管ヌール、脳卒中集中治療室、24時間体制の先進的な画像診断機関が必要である。

8. 脳外科治療と血管内治療の麻酔管理（表8）
麻酔管理のゴールは、動脈瘤再破裂のリスクを減らす血行動態管理と、脳血管虚血性障害を防ぐ刺激を含まわず、低血圧により動脈瘤再破裂を防ぐ試みがあっただけに、低血圧には早期および遅延性神経脱落徵候出現のリスクがある。脳動脈瘤手術中の高血圧は長期の認知機能や神経機能の低下を招く。破裂動脈瘤の開頭手術において低温療法が検討され、低体温は比較的安全であるものの、臨床グレードの良い症例で死亡率や転帰に影響はなかった。術中的動脈瘤破壊を防ぐため、一時的動脈閉塞と昇圧が導入されるが、その効果はまだ十分評価されていない。特定の巨大脳動脈瘤患者に超低体温と循環停止/体外心肺循環の導入が可能であるが、転帰についてのデータが乏しい。血管内治療を受ける患者の麻酔管理の文献は少ないが、破裂動脈瘤手術の開頭術の麻酔管理の原則があてはまるだろう。血管内治療における麻酔の目的の1つは、血管内処置に用いる画像撮像のためにあり、全身麻酔が選ばれることが多い。

9. aSAH後の脳血管攣縮と遅発性脳虚血の管理（表9）
血管造影でみられる脳動脈の狭小化（vasospasm：血管攣縮）はaSAH後の5〜10日最もよく起こり、21日後には消失する。血管造影でみられる主幹動脈の狭小化のうち虚血性神経徵候が50%にしかみられないが、遅発性脳虚血（DCI）、特に血管攣縮に関連したDCIは死亡と重度機能障害の主な原因となる。前回のガイドラインでは、予防法として経口nimodipineと正常血流量の維持、治療には3-H療法（血行動態増強療法）および血管拡張薬とバルーン血管形成術に焦点があてられた。その後nimodipineについては、総合的メタ解析で神経学的転帰の改善が確認された。一方、脳底動脈瘤に対する予防的な血管形成術と抗血小板薬の予防的投与は Resist 病例を低くさせなかった。脳脊髄液ドレナージによる血管攣縮とDCIの抑制効果は単一の症例コントロール研究でのみ示されている。DCIの定義には、局所低血圧を検出す血行動態検査、動脈瘤狭小化を検出す解剖学的検査、血流速度の変化を検出す経頭盖ドプラ法が用いられるが、このうち血流検査がより正確であるとのデータが出ている。最終的に脳血管攣縮やDCIの発症は、高血圧の治療により改善する。脳血管攣縮やDCIの発症は、高血圧の治療により改善する。脳血管攣縮やDCIの発症は、高血圧の治療により改善する。

10. aSAHに関連した水頭症の管理（表10）
急性水頭症はaSAH患者の15〜87%に起こり、慢性水頭症はaSAH患者の8.9〜48%に起こるとされる。aSAH関連の急性水頭症は脳室外ドレナージ（EVDか腰椎ドレナージ（LD））で治療される。LDは再出血のリスクを高めないとされるが、脳脊髄液ドレナージは適応が限定されている。この症例で、特に脳底動脈瘤手術後の患者には、LDの適応が制限される。脳底動脈瘤手術後の患者では、LDの適応が制限される。
置後に脳組織がシフトする可能性がある。慢性水頭症は通常脳室シャント術によって治療される。脳室シャント術につき、EVDが24時間使用群と96時間使用群が非作為コントロール試験で比較されたが、シャント術の必要性（63.4% 対 62.5%）には差は認められなかった。終板（lamina terminalis）開窓術がシャントを必要とする慢性水頭症を減少することが過去に報告されたが、1,973例を対象とした11件の非作為試験のメタ解析では開窓術の有無とシャントの必要性に関連がなかった。

11. aSAHに関連した痙攣発作の管理（表11）
急性期の痙攣発作の頻度は6～18%とされ、遅発性の痙攣発作も3～7%のaSAH患者にみられる。早期痙攣発作の危険因子としては中大脳動脈瘤、aSAHの厚み、脳内血腫の存在、再出血、梗塞、重篤な臨床的グレードがあげられる。日常的な抗痙攣薬の投与を支持する明確なエビデンスはないが、aSAH急性期の痙攣は脳損傷を悪化させ、未治療動脈瘤からの再出血を起こす可能性があるとの議論から、短期の抗痙攣薬の予防的投与が一般に行われている。

12. aSAHに関連した内科的合併症の管理（表12）
低ナトリウム血症はaSAH後10～30%の症例にみられる。aSAHによって惹起される中枢性塩類喪失症候群（cerebral salt wasting syndrome：CSWS）は、ナトリウム利尿薬の過剰な分泌により低ナトリウム血症を起こし、同時に循環血流量の減少も起こし易いと考えられる。vWF（因子 VIII）やコロイド液による効果的な循環血流量の回復はCSWSによる脳虚血のリスクを低下させる。3%食塩水が低ナトリウム血症を是正することが後向き調査で示唆され、フルドロコルチゾンが低ナトリウム血症と体液バランスを是正することができる2つの非作為コントロール試験で示されている。

発熱はaSAHで最も高頻度にみられる内科的合併症である。非感染性（中枢性）の発熱は脳損傷の重症度、出血量、血管挙類性の発現に関連している。aSAH後の高血糖の積極的な管理が不良な転帰のリスクを低下させることが示唆されている。貧血もaSAH後によくみられ、ヘモグロビンを高値に保つことが転帰の改善につながるとの報告がある。しかしaSAH後の最適なヘモグロビン値は未定である。ヘパリン起因性血小板減少症患者には血栓性合併症、症候性血管挙類性、DIC、不良な転帰、死亡がより高い頻度で起こる。深部静脈血栓症もaSAH後の比較的よく起こる。深部静脈血栓症のスクリーニングは無症候性血栓症の発見に有用であるが、スクリーニングの有無によって肺塞栓症の頻度は変わらない。

＊以下に掲載される表には、次の略語が用いられている。
- aSAH：aneurysmal subarachnoid hemorrhage（脳動脈瘤によるくも膜下出血）
- CSF：cerebrospinal fluid（脳脊髄液）
- CTA：computed tomography angiography（CT血管造影）
- DCI：delayed cerebral ischemia（遅発性脳虚血）
- DSA：digital subtraction angiography（デジタルサブトラクション血管造影）
- EVD：external ventricular drainage（脳室外ドレナージ）

表12 aSAHに関連した内科的合併症の管理に関する推奨

<table>
<thead>
<tr>
<th>推奨</th>
<th>エビデンスの分類とレベル</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. aSAH後の低血糖の大量投与と血管内血液容量の増加は推奨されない。</td>
<td>クラスIII,エビデンスレベルB</td>
</tr>
<tr>
<td>2. aSAH発症直後の一部の患者では、心肺蘇生、肺動脈挿管および体液を多く含む輸液を静脈内に輸液することにより、血腫の状態を改善することが報告されている。（新規推奨）</td>
<td>クラスIIa,エビデンスレベルB</td>
</tr>
<tr>
<td>3. aSAHの急性期には、正常体温を目標とし、適切な振動療法を用いて発熱を積極的に抑制することが推奨される。（新規推奨）</td>
<td>クラスIIa,エビデンスレベルB</td>
</tr>
<tr>
<td>4. aSAH発症直後の一部の患者では、低血糖を厳重に回避し、糖を慎重に管理することを検討してもよい。</td>
<td>クラスIIa,エビデンスレベルB</td>
</tr>
<tr>
<td>5. 混合赤血球の輸血を用いた輸血の治療は、脳虚血のリスクがあるaSAH患者に考慮しても良い。最も影響を及ぼすヘモグロビンの目標値はまだ決定されていない。（新規推奨）</td>
<td>クラスIIa,エビデンスレベルB</td>
</tr>
<tr>
<td>6. 新鮮凍結ドロコロドホルモンを低温保存による低ナトリウム血症の予防と対症は推奨される。</td>
<td>クラスIIa,エビデンスレベルB</td>
</tr>
<tr>
<td>7. ヘパリン性出血症の低血小板減少症の深部静脈血栓症をaSAH後には比較的多く認められる合併症である。早期発見と適切な治療が求められるが、適切なスクリーニングパラダイムの決定にはさらなる研究が必要である。（新規推奨）</td>
<td>クラスIIa,エビデンスレベルB</td>
</tr>
</tbody>
