Atherosclerotic Plaques in the Aortic Arch and Subclinical Cerebrovascular Disease

Aylin Tugcu, MD; Zhezhen Jin, PhD; Shunichi Homma, MD; Mitchell S.V. Elkind, MD, MS; Tatjana Rundek, MD, PhD; Mitsuhiro Yoshita, MD, PhD; Charles DeCarli, MD; Koki Nakamishi, MD; Sofia Shames, MD; Clinton B. Wright, MD, MS; Ralph L. Sacco, MD, MS; Marco R. Di Tullio, MD

Background and Purpose—Aortic arch plaque (AAP) is a risk factor for ischemic stroke, but its association with subclinical cerebrovascular disease is not established. We investigated the association between AAP and subclinical cerebrovascular disease in an elderly stroke-free community-based cohort.

Methods—The CABL study (Cardiovascular Abnormalities and Brain Lesions) was designed to investigate cardiovascular predictors of silent cerebrovascular disease in the elderly. AAPs were assessed by suprasternal transthoracic echocardiography in 954 participants. Silent brain infarcts and white matter hyperintensity volume (WMHV) were assessed by brain magnetic resonance imaging. The association of AAP thickness with silent brain infarcts and WMHV was evaluated by logistic regression analysis.

Results—Mean age was 71.6±9.3 years; 63% were women. AAP was present in 658 (69%) subjects. Silent brain infarcts were detected in 138 participants (14.5%). In multivariate analysis adjusted for potential confounders, AAP thickness and large AAP (≥24 mm in thickness) were significantly associated with the upper quartile of WMHV (WMHV-Q4; odds ratio =1.17; 95% confidence interval, 1.04–1.32; P=0.009 and odds ratio =1.79; 95% confidence interval, 1.40–3.09; P=0.036, respectively), but not with silent brain infarcts (odds ratio =1.08; 95% confidence interval, 0.94–1.23; P=0.265 and odds ratio =1.46; 95% confidence interval, 0.77–2.77; P=0.251, respectively).

Conclusions—Aortic arch atherosclerosis was associated with WMHV in a stroke-free community-based elderly cohort. This association was stronger in subjects with large plaques and independent of cardiovascular risk factors. Aortic arch assessment by transthoracic echocardiography may help identify subjects at higher risk of subclinical cerebrovascular disease, who may benefit from aggressive stroke risk factors treatment. (Stroke. 2016;47:2813-2819. DOI: 10.1161/STROKEAHA.116.015002.)

Key Words: atherosclerosis ● cerebrovascular diseases ● silent brain infarct ● stroke ● white matter hyperintensity

White matter hyperintensities (WMHs) and silent brain infarcts (SBIs), both manifestations of subclinical cerebrovascular disease, are commonly seen on brain magnetic resonance imaging (MRI) scans of older adults.1 In the general population, the prevalence of SBI ranges from 7% to 28%,2,3 with the elderly population at the higher end of the range. With respect to WMH, the prevalence ranges from 11% to 21% at age 64 to 94% at age 82.4,5 It has been shown that SBI and WMH share common risk factors with stroke6,7 and are strong predictors of future stroke,4,8 cognitive impairment,9,10 and dementia.9 Because of its wide variability in prevalence among older adults from different cohorts and its association with cardiovascular disease risk factors and prior stroke, subclinical cerebrovascular disease is believed to be at least partially preventable through detection and treatment of modifiable risk factors.1

Aortic arch plaque (AAP) is an established risk factor for ischemic stroke. The association between AAP and stroke risk, initially established in autopsy studies,11 was subsequently confirmed by in vivo studies that used trans-esophageal echocardiography (TEE) with a case–control12 or prospective13 design. Large plaques (defined as ≥4 mm in thickness in most studies) were proven to be strongly associated with first stroke,11,12 recurrent stroke,13 and death.14 In a previous study, aortic arch atherosclerosis was found to be associated with SBI in patients with atrial fibrillation (AF).15

and the authors suggested that microembolization of small thrombi might be the mechanism for SBI. However, little is known on the relationship between aortic arch atherosclerosis and subclinical brain disease in the general population, especially in the elderly, who have the greatest frequency of both AAPs and subclinical brain lesions. Accordingly, the aim of the present study was to investigate the association between aortic arch atherosclerosis and subclinical cerebrovascular disease in an elderly community-based cohort without prior stroke.

**Methods**

**Study Population**
The CABL study (Cardiovascular Abnormalities and Brain Lesion) is a community-based epidemiological study designed to investigate the cardiovascular predictors of silent cerebrovascular disease in the community. CABL based its recruitment on the NOMAS (Northern Manhattan Study), a population-based prospective study that enrolled 3298 participants from the community living in northern Manhattan between 1993 and 2001. The study design and recruitment details of NOMAS have been described previously.\(^1\)\(^6\) Beginning in 2003, participants were invited to participate in an MRI substudy if they (1) were at least 55 years of age, (2) had no contraindications to MRI, and (3) did not have a previous diagnosis of stroke. From September 2005 to July 2010, NOMAS MRI participants who voluntarily agreed to undergo a more extensive cardiovascular evaluation including transthoracic echocardiography (TTE) were included in CABL. Participants for whom both echocardiography and brain MRI information were available constitute the sample of the present study.

**Risk Factor Assessment**
Cardiovascular risk factors, ascertained through direct examination and interview by trained research assistants, and blood tests were also performed at the time of TTE or MRI. Hypertension was defined as a history of myocardial infarction, coronary artery bypass grafting, percutaneous coronary intervention, typical angina, or use of anti-ischemic medications. Diabetes mellitus was defined as fasting blood glucose ≥126 mg/dl or the participant’s self-reported history of hypertension or use of antihypertensive medication. Diabetes mellitus was defined as a history of diabetes mellitus or use of diabetes mellitus medications.

**Detection of Aortic Plaques**
Two-dimensional transthoracic images of the aortic arch with real-time 3-dimensional confirmation from a suprasternal window were obtained by a registered cardiac sonographer after a standardized protocol using a commercially available system (IE33; Philips Medical Systems, Andover, MA) equipped with a 2.5- to 3.5-MHz transducer. All the tests were stored on digital media for subsequent analysis. The aortic arch was defined as the portion of aorta between the curve at the end of the ascending portion and the takeoff of the left subclavian artery. A plaque was defined as a discrete protrusion of the intimal surface of the vessel at least 1 mm in thickness, different in appearance and echogenicity from the adjacent intact intimal surface (Figure 1, arrow). AAP were characterized according to previously described criteria\(^1\)\(^3\) as large (>24 mm in thickness), small (<4 mm in thickness), or not present. In case of multiple plaques, the most advanced lesion was considered. All images were interpreted by a single experienced echocardiographer (Dr Di Tullio) blinded to participant’s characteristics and risk factors.

**Brain MRI**
A detailed description of the assessment of subclinical cerebrovascular lesions has been published previously.\(^1\)\(^5\) In brief, brain imaging was performed on a 1.5-T MRI system (Philips Medical Systems). SBIs were rated by 2 of the authors (Drs DeCarli and Yoshita) and defined as either a cavitation on the fluid-attenuated inversion recovery sequence of at least 3 mm in size, distinct from a vessel (owing to the lack of signal void on T2 sequence) and of equal intensity to cerebrospinal fluid in the case of lacunar infarction, or as a wedge-shaped cortical or cerebellar area of encephalomalacia with surrounding gliosis consistent with infarction attributable to distal arterial branch occlusion. Interobserver agreement for SBI detection was 93.3%.\(^1\)\(^8\) WMH volume (WMHV) analysis was based on a fluid-attenuated inversion recovery image and performed by using the Quantum 6.2 package on a Sun Microsystems Ultra 5 workstation. WMHV was expressed as proportion of total cranial volume to correct for differences in head size. The time difference between MRI and TTE was <90 days in 591 subjects (62%). All measurements were performed blinded to participant identifying and clinical information.

---

**Figure 1.** Two-dimensional echocardiographic image from the suprasternal window of a large atherosclerotic plaque (arrow) in the distal portion of the aortic arch. The measurement of the plaque thickness (7 mm) is shown. AA indicates aortic arch; DA, descending aorta; LCA, left carotid artery; and LSA, left subclavian artery.
Statistics
WMHV was categorized in quartiles of the observed distribution, and the upper quartile (WMHV-Q4) was considered as the primary outcome in the analyses. Data are presented as mean±standard deviation for continuous variables and as percentage for categorical variables. Comparison between 2 groups (presence/absence of SBI; WMHV-Q4/WMHV-Q1-3) was carried using the Student’s 2-sided t test for continuous variables and the Chi-square test for categorical variables. One-way analysis of variance was used to compare the differences between mean values across AAP groups (no plaque, small plaque, and large plaque). Univariate and multivariate logistic regression analysis were used to assess the association between the presence of AAP thickness and SBI or the upper quartile (WMHV-Q4). No plaque was used as a reference for the AAP thickness category analysis. Variables that were associated with SBI or WMHV-Q4 in univariate analysis at the 0.1 level were entered as covariates in the multivariate analyses. Odds ratios and 95% confidence intervals were calculated. For all statistical analyses, a 2-tailed P<0.05 was considered significant. Statistical analyses were performed by using SAS software version 9.3 (SAS Institute Inc, Cary, NC).

Results
Study Population
Mean age of the study population was 71.6±9.3 years; 63% were women. AAP was present in 658 (69%) subjects; the plaque size was small (<4 mm) in 543 (57%) cases and large (≥24 mm) in 115 (12%) cases. SBI was present in 138 cases (14.5%). Mean WMHV was 0.65±0.82% (median=0.34%, interquartile range=0.52%). Clinical characteristics of the study population according to plaque presence and size are shown in Table 1. Age, sex, body mass index, hypertension, smoking history, and hypertension medication were significantly different across the groups.

Subjects with SBI were significantly older, more frequently male, and had higher frequencies of hypertension, diabetes mellitus, AF history, and use of hypertension medication (Table 2). Subjects in the WMHV-Q4 were also older, more often hypertensive, and had higher frequencies of AF history and use of hypertension medication (also Table 2).

AAP, SBI, and WMH
The prevalence of SBI was higher in subjects with small and large plaques compared with subjects with no plaque (Table 1). Mean WMHV percentage of total cranial volume increased significantly with increasing arch plaque thickness category (Table 1). The intergroup differences across AAP categories for presence of SBI and mean WMHV are shown in Figure 2A and 2B, respectively. The mean AAP thickness was also significantly higher in participants with SBI than those without (2.3±1.4 mm versus 1.9±1.5 mm; P=0.007) and in the WMHV-Q4 group than in the WMHV-Q1-3 groups (2.4±1.4 mm versus 1.8±1.4 mm; P=0.001; Table 2). Data on the association between AAP thickness categories and the presence of SBI and WMHV-Q4 are shown in Table 3. Plaque thickness was significantly associated with both SBI and WMHV-Q4 in univariate analysis. After adjustment for relevant covariates, the significance of the association was lost for SBI but not for WMHV-Q4. Similarly, the presence of small or large AAP was significantly associated with SBI in univariate analysis, but not in the multivariate models. In univariate analysis, both small and large plaques were also significantly associated with WMHV-Q4. After adjusting for covariates, large plaques remained significantly associated with WMHV-Q4, whereas small plaques showed a nonsignificant trend. The subgroup analysis in the 591 subjects with an MRI and TTE time difference <90 days showed a similar trend as in the entire population. Please see Table 1 in the online-only Data Supplement.

Discussion
In this study, we investigated the relationship between aortic arch atherosclerosis and subclinical cerebrovascular disease in an elderly community-based cohort without prior stroke. We found that AAP thickness was independently associated with WMHV, but not with SBI. The association with WMHV was stronger in subjects with large plaques.

Numerous case–control13,19 and prospective studies13,20 have confirmed the role of proximal arch plaques as risk factors for stroke and other embolic events; however, the mechanism underlying the association between AAP and WMHV is not immediately clear. The prevalence of severe AAP in stroke patients has been reported to be between 14% and 21%,19,21 and is similar to other recognized causes of embolic stroke, such as carotid artery disease, present in 9% to 17%22 of stroke patients, and AF; present in 11% to 20%.23 With respect to subclinical cerebrovascular disease, SBIs and WMHs are considered to be related but somewhat different expressions of brain disease. Although SBIs are focal areas of infarcts, presumed to result from the occlusion of a single small perforating artery supplying the subcortical areas of the brain,24 WMHs are considered areas of leukoaraiosis (loss of white matter) because of chronic hypoperfusion of the white matter and disruption of the blood–brain barrier, leading to chronic leakage of plasma into the white matter.25 Several studies showed that both conditions are associated with atherosclerotic and cardiovascular risk factors, such as hypertension, left ventricular hypertrophy, cigarette smoking, hyperhomocysteinemia, carotid plaque, arterial stiffness, and intima–media thickness.2,3,17,26,27

Epidemiological studies have hypothesized that some silent cerebrovascular disease might have a microembolic pathogenesis.28,29 In a previous study, the association between unstable carotid plaques and WMHV was examined in patients referred for carotid endarterectomy.30 Unstable plaques were associated on average with an over 2-fold increase in number of WMHV lesions in the ipsilateral hemisphere compared with stable plaques. The authors suggested that microembolism may contribute to the development of WMHV lesions and, in particular, to the development of small isolated lesions. However, the sample size was small, with the risk of unbalanced confounding risk factors between groups. Another study investigated the predictors of SBI in patients with nonvalvular AF.15 Complex aortic plaques, defined by TEE as large plaques, plaques with ulceration, or plaques with mobile components, were independently associated with the presence of SBI on brain MRI. The authors speculated that microembolization from the left atrium or advanced aortic lesions might be the cause of SBI. However, the sample size was again small (103 patients, with only 31 patients with SBI) and included only patients with nonvalvular AF, an important independent cause for embolic stroke. In line with our findings, a report from the Rotterdam
Scan Study showed that aortic atherosclerosis in mid-life, assessed by the presence of aortic calcification on abdominal radiographs, was associated with WMHs detected 20 years later; in that study, however, the relationship between aortic atherosclerosis and WMHs was lost when evaluated cross-sectionally in the elderly subjects, possibly because of the coexistence of several cardiovascular risk factors, which may decrease the discriminative power of atherosclerotic plaques.

AF indicates atrial fibrillation; MI, myocardial infarction; SBI, silent brain infarct; and WMHV, white matter hyperintensity volume.
Additionally, the study derived its plaque information from the abdominal aorta, whose link with cerebrovascular disease is less strong and direct than for the proximal aorta.

The association between AAP and WMH found in this study seems unlikely to be of thromboembolic origin. AAP thickness was not associated with SBI after adjusting for other pertinent covariates. In addition, the presence of large plaque, which is known to carry the strongest association with thromboembolic stroke, was not associated with SBIs. On the contrary, AAP thickness was significantly associated with WMH severity, defined by the upper quartile of WMHV, independent of other confounders. The association was the stronger in subjects with large plaques. One potential mechanism explaining the association of AAP with WMH, but not with SBI, might be through arterial stiffness. Aortic atherosclerosis is known to be strongly associated with arterial stiffness and increased aortic pulse wave velocity. Originally proposed by Fazekas et al as the water hammer effect and recently described by Saji et al as the Tsunami effect, increased pulse wave velocity may contribute to cerebral microcirculatory damage, which in turn may induce disruption of vascular dynamics and complicate perivascular flow, leading to WMH in the brain. Aortic arch atherosclerosis may also be a marker of diffuse atherosclerosis rather than an etiologic mechanism for subclinical cerebrovascular disease and may have a common pathogenic pathway with WMH that portends the higher stroke risk associated with either condition.

Our study has potential clinical implications. We showed that the presence of AAPs is independently associated with WMH severity, which in turn is a strong predictor of stroke, cognitive impairment, and dementia. Thus, aortic arch assessment by TTE in the elderly might contribute to identifying patients at higher risk of cerebrovascular disease, for whom more aggressive evaluation to confirm cerebrovascular disease (eg, MRI) or risk factor modification might be warranted.

**Strengths and Limitations**

The main strengths of our study are the large number of subjects studied with advanced imaging techniques (brain MRI), the wide range of cardiovascular risk profiles present in our study population, and the confirmation of our findings after adjustment for pertinent potential confounders. However, our study also has limitations. The study sample included subjects >55 years of age with a large representation of Hispanic ethnicity, which might preclude the generalization of our findings to populations with different demographic composition. However, because subclinical cerebrovascular

‡P < 0.05.
disease is more commonly found in older adults, our cohort represented an ideal setting for this study. Furthermore, the cross-sectional design of our study only allows to document associations that do not necessarily imply cause–effect relationships. We used TTE rather than TEE for AAP detection and plaque measurements. Therefore, we may have underestimated the prevalence of plaques and could not assess plaque morphology (ulceration or small mobile components), which is better assessed by TEE. However, TTE is a noninvasive technique that is better suited than TEE for use as a screening technique in asymptomatic individuals and has proven to be accurate for assessing the presence of protruding AAP in patients evaluated for detection of a source of embolism, with positive and negative predictive values of 91% and 98%, respectively. Finally, we cannot exclude that unmeasured confounders may have been involved in the observed associations.

Conclusions
Aortic atherosclerosis was independently associated with WMH severity in a stroke-free community-based cohort. This association was stronger in subjects with large plaques. Whether a more aggressive risk factor control in this subset of patients may improve their cardiovascular and cerebrovascular outcomes requires further investigation.
