Carotid Atherosclerotic Plaque Characteristics on Magnetic Resonance Imaging Relate With History of Stroke and Coronary Heart Disease

Mariana Selwaness, MD, PhD; Daniel Bos, MD, PhD; Quirijn van den Bouwhuijsen, MD; Marileen L.P. Portegies, MD; M. Arfan Ikram, MD, PhD; Albert Hofman, MD, PhD; Oscar H. Franco, MD, PhD; Aad van der Lugt, MD, PhD; Jolanda J. Wentzel, PhD; Meike W. Vernooij, MD, PhD

Background and Purpose—Because atherosclerosis is a systemic disease, presence and composition on 1 location may relate to ischemic events in distant locations. We examined whether carotid atherosclerotic wall thickness, stenosis, and plaque composition are related to history of ischemic stroke and coronary heart disease (CHD).

Methods—From the population-based Rotterdam Study, 1731 asymptomatic participants (mean age, 72.4±9.1 years; 55% males) underwent magnetic resonance imaging of both carotid arteries. We assessed carotid wall thickness, stenosis and plaque composition, that is presence of intraplaque hemorrhage, lipid, and calcification. History of ischemic stroke and CHD was assessed until date of magnetic resonance imaging. The study was approved by the institutional review board, and all participants gave informed consent. Logistic regression analyses adjusted for age and traditional cardiovascular risk factors were used to study sex-specific associations between plaque characteristics and clinical events.

Results—We found that both carotid stenosis and intraplaque hemorrhage were associated with ischemic stroke in men but not in women (men: odds ratio [OR] for stenosis [per 10% increase]: 1.17 [95% CI, 1.06–1.30] and for intraplaque hemorrhage 2.39 [95% CI, 1.32–4.35]). In both men and women, carotid stenosis was associated with CHD (men: OR per 10% increase 1.12 [95% CI, 1.04–1.21] and women: OR, 1.17 [95% CI, 1.03–1.34]) and carotid wall thickness was associated with CHD (men: OR, 1.20 [95% CI, 1.03–1.39] and women: OR, 1.21 [95% CI, 0.88–1.65]). None of the plaque components was associated with CHD.

Conclusions—Whereas carotid plaque thickness and stenosis are associated with the history of ischemic stroke and CHD, carotid intraplaque hemorrhage is associated with ischemic stroke, but not with CHD, providing novel insights into the pathogenesis of cardiovascular events. (Stroke. 2016;47:1542-1547. DOI: 10.1161/STROKEAHA.116.012923.)

Key Words: atherosclerosis ■ cardiovascular disease ■ carotid stenosis ■ magnetic resonance imaging ■ stroke

Atherosclerosis is the primary cause of cardiovascular disease, with coronary heart disease (CHD) and ischemic stroke as its most important clinical manifestations. Atherosclerosis is clinically silent for years with gradual thickening of the vessel wall and changes in plaque composition. Previous data suggest that plaque vulnerability depends on its composition, rather than on its thickness or the severity of stenosis. One of the vessel beds most extensively studied in atherosclerosis is the carotid artery because it can be easily visualized using different imaging techniques. Whereas ultrasound was for long the main modality for assessing carotid wall thickness, technical advances in other imaging modalities, especially magnetic resonance imaging (MRI), now allow a better characterization of plaque composition. Plaque components that can reliably be characterized on MRI are lipid deposits with or without a necrotic core, calcification, and intraplaque hemorrhage (IPH). Among these, IPH has gained much attention because it has been recognized as an important determinant of plaque instability and subsequent risk of stroke.

An important feature of atherosclerosis is that it is a systemic vascular disease and that the presence of atherosclerotic disease at one specific location may predict ischemic events in distant locations. In this context, intima media thickness (IMT) in the carotid arteries has previously been used to assess the risk of CHD. Also, specific properties of carotid...
plaques, such as irregularity of the plaque surface, were found to be associated with atherosclerotic plaque irregularity in other vessel beds. Subsequently, it was postulated that systemic risk factors might lead to a systemic predisposition to irregularity and rupture of atherosclerotic plaques. Such a predisposition to plaque instability attributable to systemic risk factors would suggest that plaque composition and instability in the carotid arteries could be related not only to stroke but also to other events, such as CHD. Therefore, in this study, we investigated the association of extent of carotid atherosclerosis and carotid plaque composition with a history of ischemic stroke and CHD in a population-based cohort study.

Methods

Study Population

The subjects of this study are participants of the Rotterdam Study, a prospective population-based cohort study initiated in 1990 among persons 55 years and older in the municipality of Rotterdam, the Netherlands. The original cohort of the Rotterdam Study was expanded in 2000, and again in 2006 to include participants who were 45 years and older. All study participants routinely undergo carotid ultrasonography to assess carotid IMT (measured as maximum distance between the near and far wall). Of 10073 participants with carotid ultrasonography, 3795 participants (38%) had wall thickness ≥2.5 mm in at least one carotid, which was the inclusion criterion for participating in the current carotid MRI study. From the 3795 with wall thickening we invited 2666 participants to undergo an MRI of the carotid arteries. The remaining 1129 participants had passed away, moved out of the study area, were physically disabled (n=701), or had known MRI contraindications (n=428). From the 2666 persons, 684 did not undergo MRI scanning, because of claustrophobia (n=57), physical restrictions (n=191), contraindications (n=115), refusal to participate (n=272), no show or lost to follow-up (n=49). The remaining 1982 participants (74% of those initially invited) underwent MRI scanning of both carotid arteries. Scans were excluded if image quality was bad (n=95), if no plaque ≥2 mm were observed bilaterally (n=41) or if scanning was interrupted due to claustrophobia (n=106). Of the remaining 1739 participants with carotid MRI scans, we excluded participants with incomplete information on prevalence of CHD (n=8) or stroke (n=48). The Rotterdam Study has been approved by the medical ethics committee according to the Population Study Act Rotterdam Study, executed by the Ministry of Health, Welfare and Sports of the Netherlands. A written informed consent was obtained from all participants.

Carotid MRI Scanning and Analysis of Plaque Characteristics

Imaging was performed with a 1.5-Tesla scanner (GE Healthcare, Milwaukee, WI) with a bilateral phased-array surface coil (Machnet, Eelde, The Netherlands). A standard scanning protocol was used with a total scanning time of ≥30 minutes. The carotid MRI protocol, reading, and reproducibility are described elsewhere. We evaluated both carotid arteries over a range of 15 mm caudally to 30 mm cranially of the bifurcation. We assessed plaque characteristics in all plaques with a maximum thickness of ≥2.0 mm on MRI. On the proton density weighted fast spin echo planar image, maximum carotid wall thickness was measured, and degree of luminal stenosis was calculated using the North American Symptomatic Carotid Endarterectomy Trial criteria. Plaques were reviewed for the presence of 3 different plaque components: IPH, lipid core, and calcification. In short, we defined IPH as the presence of a hypointense focus within the plaque on the 3-dimensional T1-weighted gradient echo sequence. Calcification was defined as a hypointense region in the plaque on all sequences. Finally, the presence of lipid core was defined as a hypointense region in the plaque on proton density weighted fast spin echo or proton density weighted echo planar image and T2-weighted echo planar image, or a region of relative signal intensity drop in the T2-weighted echo planar images compared with the proton density weighted echo planar image. Multiple components were permissible in one plaque.

History of Stroke or CHD

A history of ischemic stroke or CHD was based on either a history of event self-reported at study entry, verified by clinical data from the medical records, or the occurrence of an event during study follow-up but before the time of carotid MRI scanning. The follow-up system involved linkage of the study to files from general practitioners in the study area and subsequent collection of information from letters of medical specialists, brain imaging, and discharge reports in case of hospitalization. For the diagnosis of stroke and cardiac events, 2 research physicians independently coded all reported events according to the International Classification of Diseases, 10th Revision. In case of disagreement, a decision was made by a neurologist or cardiologist. Stroke was defined as a history of ischemic or unspecified stroke but not hemorrhagic stroke (International Classification of Diseases, 10th Revision codes I61, I63, and I64). To define CHD, we used a combined outcome of nonfatal myocardial infarction and myocardial revascularization (ie, percutaneous coronary intervention and coronary artery bypass grafting, International Classification of Diseases, 10th Revision codes I21, I24, and I25). Information on incidence of stroke and CHD was completed until January 1, 2012.

Assessment of Covariates

Information on cardiovascular risk factors was obtained from the visit to the research center, which took place before the MRI scanning. Smoking status was classified as ever or never. Serum total cholesterol and high-density lipoprotein-cholesterol values were measured using standard laboratory techniques. On the basis of weight and height, the body mass index was calculated. Diabetes mellitus was defined as a fasting blood glucose ≥7.0 mmol/L, nonfasting glucose ≥11.0 mmol/L, or use of antidiabetic medication. Blood pressure was measured using a random-zero sphygmomanometer at the study center visit. Hypertension was defined as a blood pressure >140/90 mm Hg or the use of antihypertensive medication. Medication dispensing data were obtained from the fully computerized pharmacies in the Ommoord suburb. Information on all filled prescriptions of antihypertensive drugs on date of carotid MRI scans was available.

Statistical Analysis

We compared the baseline characteristics between men and women using age-adjusted linear regression for continuous variables and logistic regression for dichotomous variables. We also examined the mean wall thickness and degree of stenosis in persons with and without IPH, lipid core, and calcification (Table I in the online-only Data Supplement). To investigate the relation of the different plaque characteristics (IPH, lipid, calcification, stenosis [per 10%], and carotid wall thickness) with the history of ischemic stroke and CHD, we used binomial logistic regression. Next, we analyzed these relations in the whole sample and for men and women separately. In the first model, analyses were adjusted for age, sex (in the overall model only), and carotid wall thickness (only for the analyses with IPH, lipid, and calcification as determinant). In the second models, we additionally adjusted the associations for cardiovascular risk factors (smoking, total cholesterol, high-density lipoprotein-cholesterol, body mass index, diabetes mellitus, and hypertension).

We also evaluated effect modification by sex. Finally, we performed additional analyses in which all plaque characteristics were further adjusted for the other plaque components (Tables I and II in the online-only Data Supplement).

All analyses were carried out using SPSS Statistical Package version 20.0 (Chicago, IL). Missing values in the covariates were imputed using the Expectation Maximization method.
Results

Table 1 reports the characteristics for the 1731 participants. The population consisted of 936 men (55%; mean age, 72.3±9.0 years) and 795 women (46%; mean age, 73.6±9.3 years). Men had lower total cholesterol values, lower high-density lipoprotein-cholesterol, higher prevalence of smoking, diabetes mellitus, and diastolic blood pressure. The mean carotid wall thickness was 3.6 mm (±1.1) and mean degree of stenosis was 13.1% (±18). IPH was prevalent in 35%, lipid in 41%, and calcification in 82%. Information on carotid plaque characteristics and history of CHD was available for 1731 participants and for history of stroke in 1683 participants. Before the carotid MRI scanning, a total of 105 individuals (61 men [6.5%] versus 44 women [5.5%]) experienced an ischemic stroke and 199 individuals (164 men [15.6%] versus 53 women [6.7%]) experienced a CHD event.

Table 2 presents an overall and sex-specific associations between plaque characteristics and history of ischemic stroke, adjusted for age, carotid wall thickness (model 1), and for cardiovascular risk factors (model 2). In the multivariable model (model 2), only carotid stenosis was significantly associated with stroke (odds ratio [OR] per 10% increase in stenosis 1.14 [95% CI, 1.05–1.24]). However, after we stratified for sex, we found a strong association for IPH and carotid stenosis with stroke in men but not in women (OR for IPH: men: 2.39, [95% CI, 1.32–4.35], women: 0.69 [95% CI, 0.33–1.46]). OR for stenosis per 10% increase 1.17, [95% CI, 1.06–1.30], women: 1.10 [95% CI, 0.95–1.28]). When we tested for effect modification by sex, we only found the interaction term with IPH to be significant (P=0.03). Lipid, calcification, and carotid wall thickness were not associated with stroke in the fully adjusted model.

Table 3 shows overall and sex-specific associations between plaque characteristics and history of CHD, adjusted for age, carotid wall thickness (model 1), and for cardiovascular risk factors (model 2). In the overall analysis, only carotid stenosis was significantly associated with CHD after adjustment for cardiovascular risk factors (OR per 10% increase 1.14 [95% CI, 1.06–1.22]). Stratifying for sex did not materially change this association in both men and women. Also, carotid wall thickness was significantly associated with CHD in men (OR, 1.20 [95% CI, 1.03–1.39]) but not in women (OR, 1.21 [95% CI, 0.88–1.65]). For carotid stenosis and wall thickness, no effect modification by sex was observed (data not shown). None of the various plaque components was associated with the history of CHD, also after stratification for sex. All analyses for the association between plaque characteristics and stroke and CHD were repeated with additional adjustment for the remaining plaque components, but this did not alter the results (Tables II and III in the online-only Data Supplement).

Discussion

In this population-based study, we found carotid atherosclerotic plaque characteristics to be differentially related to history of ischemic stroke and CHD. Whereas the extent of atherosclerosis, expressed as plaque thickness or stenosis, was associated both with the history of ischemic stroke and CHD, plaque composition, and specifically IPH, seemed to be associated with the history of stroke only. These associations were primarily present in men and less prominent in women.

The relationship between carotid IMT as measured with B-mode ultrasound and cardiovascular disease has been well established and IMT serves as a marker of generalized atherosclerosis.9–11 To this extent, IMT has been increasingly used for risk stratification models and contributes greatly to the prediction of CHD.10,22 Toward our knowledge, no studies have mainly focused on the relation between carotid plaque composition as detected with MRI and CHD. Most imaging studies used ultrasound measurements, because these measurements are relatively simple and noninvasive, but the resolution is of limited value for characterization of plaque composition.33 By using MRI, we found that carotid wall thickness and stenosis are more associated with a history of CHD than any of the specific carotid plaque components.

We found a prominent association of stenosis and IPH with history of stroke, which is in line with several clinical studies that investigated carotid plaque composition and neurological ischemic events.2,3,24–26 In a meta-analysis among 394 asymptomatic subjects, it was found that especially IPH was related to a substantially increased risk of stroke (hazard ratio, 3.5).2 However, because atherosclerosis is a chronic inflammatory condition with various local and systemic manifestations,27 researchers have raised the hypothesis that plaque instability may also be a systemic condition, influenced by systemic risk factors.28,29 For this reason, the term vulnerable patient was introduced, indicating that changes found in 1 vessel bed may be predictive of risk of events in another vessel bed.6,12 Whereas several reports previously suggested
a relation between carotid IPH and CHD, we did not find any significant association between any of the carotid plaque components and history of CHD. Although we used previous clinical history with no clear information on how long exactly the CHD event had occurred before the carotid artery was imaged, carotid plaque composition seemed to be less important for CHD than for ischemic stroke. A possible explanation for the discrepancy with previous literature is that some of these studies used carotid tissue specimens derived after carotid endarterectomy or autopsy, in which it is difficult to distinguish between IPH and intraluminal thrombi after the tissue preparation. Other explanations may be related with the fact that others used a composite end point of cerebral and cardiovascular disease, or did not stratify for sex. This may have resulted in a dilution of the association between IPH with stroke and an overestimation of the association with CHD. Furthermore, a precise mechanism describing how atherosclerosis in one vessel bed can lead to clinical events other than those observed after a composite end point of cerebral and cardiovascular disease, or did not stratify for sex. This may have resulted in a dilution of the association between IPH with stroke and an overestimation of the association with CHD. Furthermore, a precise mechanism describing how atherosclerosis rather than the vulnerability of the plaque. With respect to clinical events, we found that carotid atherosclerotic plaque characteristics differed between men and women. These differences could, in part, be explained by the smaller number of CHD events in women, leading to a lack in statistical power, as the estimates for the association between plaque thickness and stenosis and CHD were similar in women as in men. Alternatively, the larger OR of the association between IPH and history of stroke that we observed in men as opposed to women is in line with the male predominance of IPH as observed in several other studies. In a recent study of symptomatic patients who underwent carotid endarterectomy, IPH seemed to be associated with an increased risk of stroke and cardiovascular events in men, but not in women. A possible explanation may relate to more efficient repair, as stable, more fibrous less inflammatory, plaques were found in women, especially asymptomatic women, compared with men in histology studies. It was also suggested that although women may have similar amount of atherosclerosis, they may differ in clinical presentation of CHD or stroke because of estrogen- or genetic-related reasons.

Several strengths and limitations of our study need to be addressed. The advantages of this study are the population-based design and the large sample size. Furthermore, we focused on history of stroke and CHD separately instead of restricting the study to 1 end organ or using composite end

points. We used prevalent cardiovascular events in which symptoms of ischemia were clinically confirmed or treated. Although linkage with data from general practitioners ensured validation of the majority of the diagnoses, events that occurred before entering the Rotterdam Study were based on self-report and may, therefore, be less reliable. An important issue to consider with respect to our findings is that we specifically investigated the relation of plaque characteristics with prevalent stroke and CHD. As a consequence, we cannot infer any temporality between the determinants and the outcomes. Moreover, fatal events, in which advanced atherosclerosis is expected, were not considered in this study. This may have led to an underestimation of the association between vulnerable plaque characteristics and clinical events. In addition, lifestyle changes or medication use initiated after primary stroke or CHD may have affected atherosclerotic plaque development. This could have stabilized the atherosclerotic plaque and reduced the differences in plaque characteristics between individuals with and without a history of clinical event. However, we cannot exclude that the plaque has evolved after experiencing stroke or CHD. These considerations highlight the need for prospective studies that investigate the relation between carotid plaque characteristics and incident stroke and CHD, and determine the incremental value of carotid MRI parameters beyond the traditional cardiovascular risk factor included in, for example, the Framingham risk score.

In summary, we found that carotid plaque thickness and stenosis are associated with a history of ischemic stroke and CHD, whereas carotid IPH is only associated with a history of ischemic stroke, and not with CHD. Future studies should focus on investigating whether there is a role for carotid MRI in risk prediction and risk stratification of ischemic stroke and CHD.

Acknowledgments

The dedication, commitment, and contribution of inhabitants, general practitioners, and pharmacists of the Ommoord district to the Rotterdam Study are gratefully acknowledged.

**Carotid Atherosclerotic Plaque Characteristics on Magnetic Resonance Imaging Relate With History of Stroke and Coronary Heart Disease**

Mariana Selwaness, MD, PhD; Daniel Bos, MD, PhD; Quirijn van den Bouwhuijsen, MD; Marileen L.P. Portegies, MD; M. Arfan Ikram, MD, PhD; Albert Hofman, MD, PhD; Oscar H. Franco, MD, PhD; Aad van der Lugt, MD, PhD; Jolanda J. Wentzel, PhD; Meike W. Vernooij, MD, PhD

**Background and Purpose:** Atherosclerosis is a systemic disease, and even if only one arterial site is involved, it may be associated with events in other organs (5). In this context, we examined whether the characteristics of plaques measured with carotid magnetic resonance imaging (MRI) are associated with baseline cardiovascular disease (CVD) risk factors and the presence of subclinical plaques. We also assessed whether there are differences in the association of plaque characteristics with events between men and women.

**Methods:** We studied 1731 participants from the Rotterdam Study, a prospective cohort study that included a baseline examination of carotid MRI. We evaluated carotid plaque characteristics (attenuated fibrous cap, lipid, hemorrhage, and calcification) and their association with events (stroke, myocardial infarction, and death) over a median follow-up of 8 years. The associations were adjusted for age, sex, smoking status, hypertension, diabetes, and baseline CVD risk factors. We also evaluated whether the associations differed by sex.

**Results:** In men, the presence of a lipid-rich core in carotid plaques was associated with an increased risk of stroke (hazard ratio, 1.5; 95% CI, 1.1-2.1) and myocardial infarction (hazard ratio, 1.3; 95% CI, 1.0-1.6) compared with men without such plaques. In women, the presence of a lipid-rich core was associated with a decreased risk of stroke (hazard ratio, 0.6; 95% CI, 0.3-1.1) and myocardial infarction (hazard ratio, 0.6; 95% CI, 0.3-1.2) compared with women without such plaques. The associations with carotid plaque characteristics were stronger in men than in women.

**Conclusion:** The presence of a lipid-rich core in carotid plaques is associated with different risks for stroke and myocardial infarction in men and women, suggesting that carotid plaque characteristics may be differentially associated with the risk of future cardiovascular events in men and women.

**Keywords:** Atherosclerosis; Carotid; Stroke; Myocardial infarction; MRI; Women
的双侧颈动脉斑块均小于 2 mm（n=41）以及因为年龄超过 75 岁而中断（n=106）等情况而被除外研究。在剩余的 1739 例接受 MRI 平扫的受试者中,还排除了既往关于 CHD 病史(n=8)或卒中史(n=48)受试者。Rotterdam 研究在荷兰卫生福利健康部和荷兰卫生福利体育部研究计划,所有受试者全部签署了书面知情同意书。

颈动脉 MRI 平扫与斑块特点分析

MRI 设备: 使用 1.5T 场强的磁共振扫描仪 (GE Healthcare, Milwaukee, WI) 获取图像,这种 MRI 设备有双侧相控阵表面线圈 (Machnet, Eelde, The Netherlands), 标准平扫要求总共的扫描时间要在 30 min 左右。颈动脉 MRI 平扫操作方法、阅片和可重复性已在其他论文加以阐述。本研究评估了颈动脉分叉处向下 15 mm 和向上 30 mm 范围的双侧颈动脉,利用 MRI 分析了所有斑块中最大厚度≥ 2.0 mm 的斑块特点。在质子密度加权快速自旋回波图像中,根据北美症状性颈动脉内膜切除手术试验标准, 测量颈动脉壁的最大厚度, 计算出动脉管腔的狭窄率。斑块主要分为 3 种不同成分: IPH、脂质核心、钙化。IPH 表现为 T1 加权序列出现低信号。钙化表现为在所有序列斑块内出现低信号。脂质核心表现为 T1 加权序列快速自旋回波或质子密度加权平面回波图像和 T2 加权平回波图像出现低信号, 或者表现为与质子密度加权回波平面成像相比, T2 加权平回波平面上成像的区域的相对信号降低。单个斑块中可能包含多种成分。

既往卒中史或 CHD 病史

既往缺血性卒中史或 CHD 病史是根据患者入组前自述、经过病历档案核实,或是基于 MRI 扫描之前的随访期间出现的临床事件。随访系统的临床材料包括了受试者提供的病例材料、医学专家的信件、脑部影像学检查和住院治疗的出院小结。对于卒中和心脏事件的诊断, 2 名参与研究的内科医生独立根据国际疾病分类(ICD10)对所有被报告的临床事件进行了编码。对于有争议的病例, 最终的诊断决定由神经科专科医生或心血管专科医生做出。卒中定义为缺血性卒中或非出血性卒中 (ICD10, I61, I63, I64)。CHD定义为非致死性心肌梗死和心肌血管重建术(例如, 经皮冠状动脉介入治疗和冠状动脉搭桥术, ICD10, I21, I24, I25)。卒中和 CHD 发生率的统计于 2012 年 1月 1日前完成。

协变量分析

采用经过年龄校正的线性回归分析处理连续变量和 Logistic 回归分析处理二元变量比较男性和女性 2 组间的基线特征。对有 / 无 IPH、脂质核心及钙化的患者平均动脉壁厚度和动脉狭窄程度进行分析。在所有受试者中均校正了年龄和性别, 在女性中还额外校正了吸烟、总胆固醇、低密度脂蛋白胆固醇、体重指数、糖尿病和高血压的相关影响。本研究还评估了性别对结果的影响。在各组织中, 本研究发现仅有 IPH 有重要的意义 (P=0.03)。脂质核、钙化及颈动脉壁厚度与卒中在充分校正模型中与卒中无明显相关。

讨论

本研究基于人群的研究发现, 动脉粥样硬化斑块特征与缺血性卒中和 CHD 病史的相关性, 并校正了年龄、血压、颈动脉壁厚度 (模型 1)、心血管危险因素 (模型 2)。在校正心血管危险因素后的总体分析中显示仅有颈动脉狭窄与 CHD 病史密切相关 [OR 值在颈动脉狭窄率每增加 10% 为 1.14 (95% CI, 1.06~1.22)]。对性别分层分析并没有在本质上改变不同性别中斑块特点与 CHD 病史之间的相关性。同时, 颈动脉壁厚度与男性患 CHD 密切相关 [OR 值, 1.20 (95% CI, 1.03~1.39)] 而与女性却无相关性 [OR 值, 1.21 (95% CI, 0.88~1.65)]。对于颈动脉狭窄和血管壁厚度, 无性别相关性(数据未显示),任何一种斑块成分与 CHD 病史无明显相关,经过性别分层校正后亦无关联。对于斑块特点与卒中史和 CHD 病史的相关分析, 由于某些影响因素未完全校正, 其结果仍存在一定局限性。
合并症。

本研究发现，颈动脉动脉粥样硬化斑块特征在临床事件发生方面存在性别差异，其原因可能是由于女性人群中患 CHD 的人数较少，缺乏统计学效力，但斑块厚度和狭窄在男性和女性没有差别。另外，本研究中男性患者IPH 与卒中病史相关的统计学数据出现较大 OR 值，但缺乏统计学效力，但斑块厚度和狭窄在男性和女性没有差别。还有一些研究提示，女性由于存在雌激素或遗传性因素等原因，在动脉粥样硬化程度相似情况下，其 CHD 和卒中的临床表现上可出现明显差异。

本研究的优点和局限性如下：

优点：(1) 本研究是基于人群的研究，且样本量较大。(2) 本研究涵盖了的心血管事件均是经过确诊和治疗的。

局限性：(1) 尽管研究者尽最大可能确保绝大多数患者诊断的准确性，但在入组前的心脑血管事件均是来自受试者口述，可信性略差。(2) 由于本研究的重点是针对颈动脉斑块特征与卒中和 CHD 患病率的相关性，但某些终点事件如卒中和 CHD 无明显相关性。下一步研究应着眼于颈动脉 MRI 检查在缺血性卒中和 CHD 预测和风险分层的作用。卒中和 CHD 的风险预测和风险分层的作用。卒中和 CHD 的风险预测和风险分层的作用。卒中和 CHD 的风险预测和风险分层的作用。卒中和 CHD 的风险预测和风险分层的作用。卒中和 CHD 的风险预测和风险分层的作用。
