Neurological Outcome of Prolonged Coma Survivors of Out-of-Hospital Cardiac Arrest

PHILIP R. YARNELL, M.D.

SUMMARY Nine adult survivors of out-of-hospital presumed cardiogenic cardiac arrest, who remained unresponsive for longer than their third hospital day and who eventually were discharged from the acute care hospital, are reported. Their neurological outcome fell into three distinct categories: (a) a persistent vegetative state, (b) able to follow some simple commands but requiring total nursing care, and (c) able to perform most activities of daily living but unemployed because of marked organic mental deficits.

With the ever increasing availability of community comprehensive medical emergency systems, many more patients are being resuscitated from out-of-hospital cardiac arrest.1,2 The survivors usually fall within several broad groupings. There are those patients who awake within the first few hospital days, those who succumb to their illness during the acute hospitalization, and those who have a prolonged period of unresponsiveness but do leave the acute care hospital. It is this last group that often causes a major concern regarding long-term neurological prognosis.

The neurological outcome at maximal improvement was examined in an adult group of out-of-hospital cardiac arrest survivors who remained unresponsive to simple verbal commands through at least the first three hospital days, and who were eventually discharged from the acute care hospital.

Patient Analysis

Partial illness profiles of nine adult survivors of non-hospital cardiac arrest who remained unresponsive through at least their third in-hospital day, but yet were able to leave the acute care hospital, are summarized in table 1. These patients represent the prolonged coma cardiac arrest survivors of 137 presumed cardiogenic cardiac arrest admissions in the 25-month period, January 1973 through January 1975, at our acute care emergency hospital. These patients had all been evaluated by the neurology service during their acute illness. All the long-term responsive survivors were personally examined in follow-up visits, except for Patient No. 9 who resided at a great distance. In his case, physician and family evaluations were used for follow-up.

The patients' age, sex and race are stated in table 1. Patient Nos. 1, 4, 8, and 9 had essentially benign cardiopulmonary histories except for mild hypertension in Patient Nos. 4 and 8. Patient No. 2 probably had had prior arrhythmias, and Patient No. 6 had a prior myocardial infarction. Patient Nos. 3 and 7 had histories of pulmonary illness while Patient No. 5 had a post-traumatic seizure disorder. Despite alcoholism being a concomitant diagnosis in approximately 50% of our medical admissions, none of these patients had this problem.

The initial cardiac rhythm recorded in the emergency room was ventricular fibrillation in Patient Nos. 3, 6, and 7. Asystole was initially recorded in Patient Nos. 2, 4, 5, 8 and 9. These data for Patient No. 1 were uncertain.

The initial neurological status was determined after the patients arrived in the coronary care unit from their emergency room resuscitation. Most patients were in a state of hypertonic unresponsiveness while Patient No. 1 was flaccid and Patient No. 5 was flaccid with intermittent myoclonic seizures. In other patients, seizures either at the time of cardiac arrest (Patient Nos. 1 and 7) or shortly after hospitalization (Patient No. 4) were noted. Only Patient No. 5 had initially nonreactive pupils, while abnormal or absent oculolcochlear or caloric responses were documented in Patient Nos. 2, 3, 4, 5 and 9 initially. All patients regained oculolcochlear and pupillary responses at maximal improvement. Post-resuscitation respiration was considered intact in seven patients. Patient No. 2 was said to breathe sporadically while Patient No. 6 had a post-resuscitation flail chest.

CSF was examined in seven of the patients. EEG was performed in all, with the first recording occurring between Day 2 and Day 8. Various neuroradiological examinations including radioisotopic dynamic and static scintigrams, pan cerebral angiography and computerized axial tomography were performed as noted in table 1.

On discharge, acute myocardial infarction had been clinically documented in Patient Nos. 1, 3, and 4. Patient No. 9 was found to have a "midsystolic click syndrome." Patient Nos. 2, 5, 6, 7 and 8 were discharged with the diagnosis of cardiac arrest of undetermined etiology.

At follow-up, Patient Nos. 2, 4, 5 and 6 had remained in a persistent vegetative state. They had regained what is considered brain stem level function but had no recognizable cortical function as judged behaviorally. All died within a three-week to four-month period after their arrest. Post-mortem examinations were performed on two patients. Patient No. 2 showed left ventricular hypertrophy, and cerebral edema with acute ischemic alterations and focal chronic ischemic alterations. Patient No. 6 showed an extensive old left ventricular infarction, and diffuse subcortical gliosis, with spousiousness in the brain. Two patients had regained the ability to comprehend and follow some simple commands but were spastically quadriparetic, incontinent, unable to swallow and totally dependent. Patient No. 1 died after 22 months of this existence in a nursing home while Patient No. 8 was being totally cared for in his home at six-month follow-up. Patient Nos. 3, 7, and 9 were ambulatory and independent in most activities of daily living at six-month to one-year follow-up. However, mentation and personality changes consisting of marked inability to retain new...

**Discussion**

In 1959, Bokonjic and Buchtal\(^4\) stated that the critical duration of postanoxic unconsciousness for total recovery was 48 hours in cardiac arrest. Beyond this time, there was an irreversible clinical deficit in their patients.\(^4\) Little appears changed in the intervening years as our current data reaffirm their conclusion. Moreover, by extending the dura-
Neurological findings of only reflex motor responsiveness, at best, shortly after arriving on the intensive care ward were found in all our patients and supported a previous report of worse final outcomes. In examining the first noted cardiac rhythms in the emergency department, two of the three ambulatory survivors had normal findings, suggesting that cardiac arrest was the cause of coma. However, in one case, the cardiac arrest was secondary to midsystolic click syndrome.

Sexual orientation of postarrest unresponsiveness to three days, our patient population amplifies the clinical deficits. Our patients fell into three distinct survival categories: four patients remained in a persistent vegetative state, two patients were able to follow simple commands and recognized familiar persons but needed total nursing care, while three patients were mostly independent in the activities of daily living but were unemployable because of major organic mental defects. Others have noted similar postarrest coma findings. Neurological findings of only reflex motor responsiveness, at best, shortly after arriving on the intensive care ward were found in all our patients and supported a previous report of worse final outcomes. In examining the first noted cardiac rhythms in the emergency department, two of the three ambulatory sur-
vivors were in ventricular fibrillation, while three of the four persistent vegetative coma patients had straight line electrocardiograms. Perhaps asystole correlates with a longer or a more severe cerebral anoxic insult, as it is believed to yield a more difficult resuscitation.\textsuperscript{1, 8} This correlation remains to be tested prospectively with in-the-field cardiograms and longitudinal evaluations.

The possibility that both the cardiac arrhythmia and neurological sequelae resulted from a primary cerebral process, i.e., hemorrhage,\textsuperscript{9} appears to be excluded by the history, course and neurological laboratory findings. However, Patient No. 5, an epileptic, still remains suspect of having a nervous system-initiated arrest with the possibility of seizures leading to a lethal cardiac arrhythmia.\textsuperscript{10} The neurological laboratory examinations were useful for exclusion and follow-up rather than diagnosis. In Patient No. 5, the third-week radioscintigram demonstrated bilateral watershed infarcts consistent with post-cardiac arrest anoxic damage,\textsuperscript{11} while Patient No. 3 demonstrated decreased right brain perfusion on his one-year radioscintigram study. Thus, in none of the long-term survivors could primary cerebral disease be found culpable of causing the neurological outcome.

The initial EEG did not differentiate early between the three categories of prolonged coma survival. The records ranged from periodic delta to continuous alpha. There were no isoelectric tracings. Perhaps very early post-arrest and serial tracings, along with using more recently described refined techniques, will prove more informative prognostically.\textsuperscript{12}

The documented acute myocardial infarction in one-third of this group of patients is in accord with the characteristics noted in a recent comprehensive survey of cardiac arrest survivors.\textsuperscript{13}

The cerebral pathology of the two autopsied patients was consistent with known cerebral stagnant anoxic insult.\textsuperscript{14}

The amnestic phenomena and personality alterations are well-known sequelae of brain injury.\textsuperscript{15}

These patients most probably would have failed to survive their out-of-hospital cardiac arrest without the modern emergency ambulance systems. Also, the cardiac care unit enhances the abilities of the initial resuscitation survivors to leave the acute care hospital.\textsuperscript{16} However, the immediate successes here are overshadowed by the severe neurological sequelae in the prolonged coma group. Hopefully, in the future, better definition of the existing cerebral insult at the initiation of resuscitation and the development of more effective therapy of the post-arrest cerebral injury may limit the number of neurologically devastated survivors.

Acknowledgment

Dr. Philip Oliva, Director of Cardiology, Denver General Hospital, provided the total list of cardiac arrest admissions from which our patients were drawn.

Dr. Avrum Organick, Director of the Medical Service, Denver General Hospital, helped make possible the milieu to do this work.
