Angiographical Extravasation of Contrast Medium in Hemorrhagic Infarction

Case Report

TADAYOSHI IRINO, M.D., MAMORU TANEDA, M.D., TAKAO MINAMI, M.D., AND YOSHIO MURATA, M.D.*

SUMMARY Leakage of the contrast medium was noted on angiograms of a patient whose autopsied brain disclosed typical pathological findings of hemorrhagic infarction. The case was a 63-year-old woman with mitral valve failure, who suddenly had loss of consciousness and right-sided hemiplegia. The left carotid angiography performed six hours after onset demonstrated middle cerebral arterial axis occlusion, and the second angiography performed three days after onset displayed recanalization of the initially occluded artery as well as extravasation of the contrast medium. Fourteen days after onset the patient died and an autopsy was performed. The brain demonstrated perivascular punctate hemorrhages in the area supplied by the middle cerebral artery, and neither hematoma nor microaneurysm was disclosed pathologically.

A short discussion is given on the possible relationship between recanalization and hemorrhagic infarction. The clinical assessment of hemorrhagic infarction has not been established successfully.

ANGIOGRAPHICAL EXTRAVASATION of the contrast medium in various kinds of intracranial hemorrhagic lesions has been reported previously by many authors regarding cases of hypertensive intracerebral hemorrhage, ruptured aneurysm, or arteriovenous malformation, and epidural hematoma. However, as yet, no cases have been described concerning angiographical extravasation in patients with occlusive cerebrovascular diseases, in spite of the fact that hemorrhagic infarction develops frequently in the clinical course of such patients. The present case demonstrated leakage of the contrast medium on the angiograms obtained after spontaneous recanalization of the occluded middle cerebral arterial axis, and the autopsied brain displayed typical hemorrhagic infarction in the infarcted area. We believe this case represents the first angiographical demonstration of extravasation in hemorrhagic infarction.
During her life, the neurological deficits did not show remarkable improvement, while consciousness gradually improved day by day. Cardiac failure developed progressively and she died of heart failure on the fourteenth day after onset.

A complete autopsy was performed. Examination of the brain disclosed the presence of perivascular miliary punctate hemorrhages in the distribution of the middle cerebral artery, especially in the basal ganglia. No solid hematoma as seen in cases of hypertensive hemorrhage was present. Neither microaneurysms nor arteriovenous malformations were demonstrated pathologically. The autopsied brain is shown in figure 4. The heart displayed mitral stenosis and a large thrombus was found on the left atrial wall.

Discussion

It is a well-known fact that spontaneous recanalization of an occluded artery, as shown in this case, frequently occurs in cerebral infarction, especially in cases of cerebral embolism associated with atrial fibrillation. However, as yet, the influence of recanalization on the prognosis has not been discussed thoroughly in the literature. On the other hand, some circumstances favoring the development of hemorrhagic infarction are known by experimental and pathological observations, and it has been said that this pathological change develops after complete ischemia, when circulation is restored before the tissues become completely necrotic. Therefore, it might be reasonable to presume that the angiographically demonstrated circulatory restoration after recanalization in the present case participated in the development of hemorrhagic infarction.

The pathological findings of hemorrhagic infarction differ from other types of intracerebral hemorrhages by fine, punctate hemorrhages of the infarcted cortex or gray nuclei. This autopsied brain displayed typical findings of hemorrhagic infarction, and neither hematoma nor microaneurysm (which were not infrequently seen in cases of intracerebral hemorrhage) was noted. Thus, the cause of the present extravasation would have been damaged endothelium, allowing a diapedesis of erythrocytes as well as leakage of contrast medium.

In the present case, leakage of the contrast medium was much more apparent in AP views than in lateral views. It might be because AP and lateral views were not obtained at the same time, or because the detection of the extravasation was easier in the AP views especially in the present case. Anyway, it is assumed that the extravasation of the present case with hemorrhagic infarction was less notable than those of the reported cases of hypertensive intracerebral hemorrhage.

Although hemorrhagic infarction has been surveyed through a large number of experimental and pathological investigations, the clinical assessment of hemorrhagic infarction has not been established successfully. Angiographical demonstration of the extravasation in hemorrhagic infarction has never been reported previously.
FIGURE 2. Serial left carotid angiograms on the third day after ictus (AP view) demonstrated recanalization. Pictures taken two seconds (a), three seconds (b), five seconds (c), and seven seconds (d) after injection of contrast medium are illustrated. Figures 2b and c demonstrate extravasation (arrow) of contrast medium from a lenticulostriate artery.

Acknowledgment
We wish to express our thanks to Kazuo Hara, M.D., Masahiro Mizukami, M.D., and Koichi Yamaguchi, M.D., for much guidance in this report.
