Magnetic Resonance Angiography of Cerebral Arteries After Neonatal Venoarterial and Venovenous Extracorporeal Membrane Oxygenation

Jeroen Hendrikse, MD, PhD; Linda S. de Vries, MD, PhD; Floris Groenendaal, MD, PhD

Background and Purpose—In newborns with severe respiratory failure, extracorporeal membrane oxygenation (ECMO) has been proven to improve survival. With venoarterial ECMO, the right common carotid artery is ligated, whereas with venovenous ECMO, this carotid artery remains intact. The authors present the magnetic resonance angiography (MRA) evaluation of cerebral hemodynamics in a case of venoarterial and a case of venovenous ECMO.

Methods—With 2D phase-contrast MRA flow volume (mL/min), measurements are obtained of the brain feeding arteries and draining veins. Time-of-flight and flow-directional MRA are used to demonstrate the anatomy and flow patterns at the level of the circle of Willis.

Results—A total volume flow of 63 mL/min at the skull base and collateral flow via the anterior circle of Willis were measured in the infant after venoarterial ECMO, and a total volume flow of 86 mL/min and a fetal type configuration of the circle of Willis were observed in the infant after venovenous ECMO.

Conclusion—MRA is a useful technique to quantify cerebral blood flow in neonates after venoarterial or venovenous ECMO and could be used to select neonates with insufficient collateral compensation after venoarterial ECMO, requiring revascularization surgery. (Stroke. 2006;37:000-000.)

Key Words: carotid arteries • extracorporeal membrane oxygenation • magnetic resonance angiography • occlusion

In newborns with severe respiratory failure, extracorporeal membrane oxygenation (ECMO) has been proven to improve survival.1 The combination of the pre-existent severe hypoxia and the ECMO procedure itself with ligation of the right common carotid artery may result in brain lesions in 20% to 50% of the neonates.1 To prevent ischemic complications, revascularization surgery has been performed after venoarterial ECMO.2 Alternatively, ligation of the common carotid artery can be prevented by venovenous ECMO, with a purely venous access in the circulation. A flow velocity comparison with ultrasound between venoarterial and venovenous ECMO demonstrated decreased intracranial flow velocities during venoarterial and preserved flow velocities during venovenous ECMO.3

In our institution, a routine MRI examination is performed after an ECMO procedure to evaluate the presence of ischemic brain damage. Advantages of MRI examination after an ECMO procedure are the potential of a combined evaluation brain anatomy and the cerebral hemodynamics with magnetic resonance angiography (MRA) techniques. We report the results of MRA measurements of flow volume (mL/min) collateral flow and vascular anatomy in 2 full-term neonates, 1 after venoarterial ECMO and 1 after venovenous ECMO.
arterial flow was measured of 95 mL/min, with a volume flow of 61 mL/min for the left common carotid artery, 24 mL/min for the right vertebral artery, and 10 mL/min for the right vertebral artery. The total venous volume flow draining via the left jugular vein below the level of the carotid bifurcation was 97 mL/min. The time-of-flight MRA, planned parallel to the circle of Willis, demonstrated occlusion of the right ICA (Figure 2A). Flow-directional–sensitive MRA images demonstrated collateral filling of the right middle cerebral artery via the anterior part of the circle of Willis, with reversed flow in the precommunicating segment (A1) of the right anterior cerebral artery (Figure 2B and 2C). No collateral flow was detected via the right posterior communicating artery.

Patient B
In patient B (birth weight 3500 g), venovenous ECMO without ligation of the right common carotid artery was performed because of meconium aspiration syndrome. Anatomical MRI performed at 3 weeks and 3 days postnatal age demonstrated a small sub cortical parietooccipital ischemic lesion on the right side. Using 2D PC MRA, the total arterial volume flow measured at the skull base was 86 mL/min, with a 33 mL/min contribution of the right ICA, 37 of the left ICA, and 16 mL/min of the basilar artery. Below the carotid bifurcation a total arterial volume flow was measured of 115 mL/min, with a 28 mL/min contribution of the right jugular vein and 93 mL/min contribution of the left jugular vein. The time-of-flight MRA demonstrated a fetal type circle of Willis, with filling of the right anterior, middle, and posterior cerebral artery from the right ICA, with a hypoplastic precommunicating segment (P1) of the right posterior cerebral artery (Figure 3A). Flow-directional–sensitive MRA images demonstrate anterior to posterior flow via the right posterior communicating artery in accordance with the dominant feeding of the right posterior cerebral artery from the right ICA (Figure 3B and 3C).

**Discussion**

In the current study, 2D PC MRA was used for volume flow (mL/min) measurements in the brain feeding arteries. With 2D PC MRA, the blood flow velocity–induced changes in magnetic resonance (MR) signal (phase shift) are exploited to measure cerebral blood volume quantitatively. As demonstrated, MRA volume flow measurements can be added to existing MR protocols, with an additional scan time of ≈40 s for combined volume flow measurements of the ICAs and basilar artery. Alternatively, arterial volume flow measurements in the extracranial arteries in preterm and term neonates can be performed with color duplex sonography. When MRI is routinely performed for detailed anatomical evaluation in the follow-up of an ECMO procedure, adding the described MRA scans provides quantitative information of flow through arteries and veins (Figure 1) and detailed information of the intracranial vasculature. The mean total volume flow of 95 mL/min for neonate A and 115 mL/min for neonate B was measured.

A previous study demonstrated the use of time-of-flight MRA for anatomical evaluation of the circle of Willis after ECMO.7 In addition to flow quantification, we combined anatomical MRA images with flow-directional–sensitive MRA at the level of the circle of Willis. With anatomical and functional information, we demonstrate collateral flow from the contralateral ICA via the anterior communicating artery and flow direction in a fetal variant type circle of Willis. Visualization of the intracranial vasculature is important because 50% of the neonates has a variant type of the circle of Willis.8 Potentially, neonates with a variant type circle of Willis, such as a missing or hypoplastic precommunicating segment (A1) of the anterior cerebral artery or a fetal type feeding of the posterior cerebral artery, will be more vulnerable for ischemia after venoarterial ECMO with less collateral capacity.

In the present study a velocity encoding of 30 cm/s was used to benefit from the full dynamic range of the 2D PC MRA for volume flow measurements with relatively low flow velocities. The pixel size of the 2D PC MRA scans of 1 mm (mean±SD) to avoid potential underestimation of flow measurements. Previously, validation studies have demonstrated the quantitative accuracy of 2D PC MRA for volume flow measurements in the brain feeding arteries,4,9 and comparisons have been made between MR PC flow quantification and ultrasound flow measurements.10

In conclusion, intracranial and extracranial volume flow measurements are reported in 2 neonates after an ECMO procedure. Collateral flow via the anterior circle of Willis is demonstrated in patient A after venoarterial ECMO, and a fetal configuration of the circle of Willis is demonstrated in patient B with a venovenous ECMO. MRA may be used in future studies to select neonates with insufficient collateral compensation after venoarterial ECMO requiring revascularization surgery.
