Caregiving Strain and Estimated Risk for Stroke and Coronary Heart Disease Among Spouse Caregivers: Differential Effects by Race and Sex

William E. Haley, PhD; David L. Roth, PhD; George Howard, DrPH; Monika M. Safford, MD

Background and Purpose—Psychosocial stress has been widely studied as a risk factor for stroke and coronary heart disease (CHD) but little is known about the differential effects of stress on stroke and CHD risk by race and sex. Caregiving for a disabled spouse has been associated with increased mortality and CHD risk, but the association of caregiving strain with stroke and CHD risk across race and sex is unknown.

Methods—Participants in the REasons for Geographic and Racial Differences in Stroke (REGARDS) study who were providing in-home caregiving to a disabled spouse reported on caregiving strain (high, some, or none), depressive symptoms, social network, education, and age. Caregiving strain groups were compared on the Framingham Stroke Risk Score (N=716) and Framingham CHD Risk Score (N=607), which estimate the projected 10-year risk of incident stroke and ischemic heart disease, respectively.

Results—High caregiving strain was associated with a 23% higher covariate-adjusted estimated stroke risk (11.06% for caregivers with no strain versus 13.62% risk for high-strain caregivers). This association was stronger in men, particularly African American men with high caregiving strain (26.95% estimated 10-year stroke risk). Caregiving strain was not associated with CHD risk scores.

Conclusions—Caregiving strain is significantly associated with higher estimated stroke risk with greatest effects for men, particularly African American men, providing caregiving to their wives. Male spouse caregivers may need special caregiving support. Prospective longitudinal studies should examine how sex and race may moderate the impact of stress on stroke and CHD risk. (Stroke. 2010;41:331-336.)

Key Words: caregiving stress ■ epidemiological studies ■ family caregiving ■ stroke risk

Psychosocial stress has been widely studied as a risk factor for cardiovascular disorders, including coronary heart disease (CHD) and stroke. A review of the relationship between psychosocial stress and cardiovascular disease concluded that a top priority for future research should be examining whether psychosocial stress is a differential risk factor by race. This is particularly important given the widely documented racial differences in both CHD and stroke and indications that psychosocial stress may be a particularly important risk factor for African Americans.

Among the psychosocial risk factors that have been studied to date, one important factor is family caregiving stress. This is a common stressor with approximately 12% of Americans aged >45 years reporting family caregiving responsibilities. High caregiving stress has been associated with poor physical and psychological health in a large number of studies and with increased mortality among spouse caregivers in one study.

We have identified 2 studies examining the relationship between family caregiving stress and risk for CHD but no such studies focusing on risk for stroke. Both projects used data from the Nurses Health Study. One found increased risk of CHD onset or death among spouse caregivers. Another study found increased risk of CHD onset or death among caregivers of grandchildren and children. Neither study examined race as a predictor variable, and sex could not be examined because the Nurses Health Study focused only on women.

Besides caregiving stress, several other psychosocial risk and protective factors have been studied as risk factors for CHD and stroke. Depressive symptoms, lack of social support, and low socioeconomic status have been widely shown to predict risk of CHD. However, there are fewer studies of these risk factors in stroke, and some critics have suggested the increased risk of stroke related to socioeconomic factors may be explained by traditional risk factors.
One reason that it has been difficult to study the differential impact of stress by race is that there have been few large, racially diverse samples on which there are measures of psychosocial stress and risk for stroke and CHD. The REasons for Geographic and Racial Differences in Stroke (REGARDS) study is an ongoing epidemiological study of stroke and CHD incidence and mortality using a large national sample of African American and white adults ≥45 years of age. The REGARDS baseline telephone interview included key questions about caregiving responsibilities and caregiving strain as well as important factors that should be examined as covariates. Thus, we have the capacity to identify caregivers, including the subgroup of caregivers who report high strain, and to compare these variables with stroke and CHD risk scores.

In this article, we examine the relationship of caregiving strain to well-validated indices of stroke and CHD risk. We focused on a highly stressed subgroup of caregivers, those caring for and coresiding with spouses, because previous research has documented that this is a very high-risk caregiving group.6,7 In addition, we examined the role of depressive symptoms, social network, education, and age, which are also potential predictors of risk. Although women have been found to show more psychological distress with caregiving than men,16 and African Americans sometimes report less psychological distress than whites,17 there are few studies examining the differential impact of sex and race on the impact of stress on physical health indicators.

Materials and Methods

Participants

Potential participants for the REGARDS study were randomly selected from a commercially available nationwide list using a stratified random sampling design. Approximately half of the sample was obtained from the “stroke belt” region (the states of Alabama, Arizona, Georgia, Louisiana, Mississippi, North Carolina, South Carolina, and Tennessee) and the remaining half from other areas throughout the 48 contiguous states with an effort to include approximately half African American and half white as well as half male and half female. After mail contact, a subsequent telephone contact was attempted. Respondents were briefly screened for eligibility and then invited to participate. Exclusion criteria included age <45 years, self-identified race other than African American or white, previous diagnosis of cancer requiring chemotherapy, inability to communicate in English, or residence in or on a waiting list for a nursing home. Anyone not excluded by these criteria was eligible for enrollment. The cooperation rate (the proportion of known eligible participants who agreed to be interviewed) was >60%.18

The sampling, recruitment, and telephone interviewing procedures for REGARDS have been described in more detail elsewhere.19 The procedures used to collect these measures are described in greater detail elsewhere.19

Instruments

Depressive Symptoms

The 4-item short form of the Center for Epidemiological Studies–Depression scale was used to assess depressive symptoms.20 Participants indicated how many days during the past week they felt depressed, lonely, sad, or had crying spells. Response options included <1 day, 1 to 2 days, 3 to 4 days, or ≥5 days. Total scores ranged from 0 to 12 with a score of ≥4 suggestive of significant psychological distress. The reliability and validity of the 4-item short form of the Center for Epidemiological Studies–Depression scale have been shown to be sufficient in comparison with the full 20-item Center for Epidemiological Studies–Depression scale.20

Social Network

A single-item indicator, a report of how many friends and relatives that the participant sees at least once per month, was used to indicate size of the social network.

Stroke Risk

The Framingham Stroke Risk Score was developed to predict 10-year risk of stroke based on data from the Framingham study.21,22 The profile uses the following variables: age, systolic blood pressure, antihypertensive medication, current cigarette smoking, diabetes, history of cardiovascular disease, atrial fibrillation, and left ventricular hypertrophy as indicated by a 7-lead electrocardiogram for the first 25% of the participants and a 12-lead electrocardiogram for the remaining 75% of the participants.

CHD Risk

The Framingham CHD Risk Score was developed to predict 10-year risk of onset of CHD or CHD death based on data from the Framingham study.23 The score uses the following variables: age, total cholesterol, high-density lipoprotein cholesterol, systolic blood pressure, diabetes, and current cigarette smoking.

Caregiving Variables

Each participant was asked: “Are you currently providing care on an ongoing basis to a family member with a chronic illness or disability? This would include any kind of help such as watching your family member, dressing or bathing this person, arranging care, or providing transportation.” Respondents who answered affirmatively to this question were categorized as “caregivers” and subsequently asked (1) how they were related to their care recipient; (2) whether they lived in the same residence with the care recipient; and (3) how much of a mental or emotional strain it was on them to provide this care. Response options for the caregiving strain question were the same as those used by Schulz and Beach24 and included “no strain,” “some strain,” or “a lot of strain.”

Statistical Analyses

Multiple regression analyses were conducted using SAS PROC Reg and SAS PROC GLM to identify the unique predictors of Framing-
ham stroke risk and CHD risk scores. The independent or predictor variables were age, sex, race, education, depressive symptoms, social network, and caregiving strain. Age was centered by subtracting out the mean age of 68 years for these 767 spouse caregivers. In our multiple regression models, we first estimated models with these main effects and then added interaction effects for sex*race, sex*caregiving strain, race*caregiving strain, and sex*race*caregiving strain to determine if any caregiving strain main effects were differentially moderated by sex or race subgroups.

### Results

Table 1 summarizes the descriptive information for the 767 participants included in our analyses, including 716 for whom stroke risk scores could be calculated and 607 participants for whom CHD risk scores could be calculated. Men were older, had lower depression scores, and were less likely to report high caregiving strain than women, but there was no significant race difference on these items. African Americans also had lower educational attainment than whites, an effect that was stronger for men than women. Because of race and sex differences on many of the variables in Table 1 and previous research suggesting associations between these factors and stroke and CHD risk, these variables were used as covariates in our analyses.

#### Predictors of Stroke Risk Scores

Significant main effects for predicting stroke risk scores are summarized in Table 2. Higher stroke risk scores were associated with greater age, male sex, African American race, less education, greater depressive symptoms, and high caregiving strain. When we applied the regression results, the model-predicted stroke risk score (or covariate-adjusted stroke risk mean score) for the high strain caregivers was 13.62%, which represents a 23% increase over the 11.06% model-predicted stroke risk score for the no-strain caregivers.

The subsequent model, including interaction effects, revealed statistically significant 2-way interactions for sex*race (F[1,677]=8.77, P=0.003) and for sex*caregiver strain (F[2,677]=6.38, P=0.002). Both of these 2-way interactions were embedded in a statistically significant 3-way interaction for sex*race*caregiving strain (F[2,677]=3.17, P=0.04). The 3-way interaction and embedded 2-way interactions are illustrated in the Figure, where it is evident that the high-strain African American male caregivers had by far the highest covariate-adjusted stroke risk score of 26.95%. This adjusted stroke risk score was >10 points higher than that for any other race–sex group.
Predictors of CHD Risk Scores

Significant main effects from the multiple regression analysis predicting CHD risk scores are summarized in Table 3. Higher CHD risk scores were associated with greater age, male sex, and greater depressive symptoms. Race, number in the social network, and caregiving strain were not found to be related to CHD risk scores. A college education was associated with somewhat reduced CHD risk compared with participants with less than a high school education. The expanded model that included 2-way and 3-way interactions for caregiving strain indicated that none of the interaction effects were statistically significant.

Supplemental Analyses

To better understand the significant relationship between caregiving strain and stroke risk scores, we examined the relationship between caregiving strain and each of the component variables that comprise the stroke risk score. We conducted univariate analyses of variance or $t$ tests to ascertain whether any of these components of the stroke risk score were significantly associated with caregiving strain. Of the 8 components, only age was significantly associated with caregiving strain ($F_{[2,713]} = 4.46, P = 0.01$) with high-strain caregivers (mean = 65.8 years) being significantly younger than moderate strain (mean = 68.4 years) and no-strain (mean = 68.5 years) caregivers. Thus, by including age as a covariate in our multiple regression models and examining age-adjusted stroke risk scores, this allowed the caregiving strain relationship with estimated stroke risk scores to emerge as statistically significant.

We used education as our primary indicator of socioeconomic status because it better reflects lifelong socioeconomic status than income among older, largely retired populations and because there was more missing data on income than on education. Supplemental analyses using income as a covariate replicated the findings reported here.

Discussion

Our results show that, after adjusting for demographic covariates, highly strained spouse caregivers have significantly elevated stroke risk scores on the Framingham Stroke Risk Score compared with spouse caregivers reporting no caregiving strain. This risk was highest for highly stressed caregiving husbands, with highly stressed African American caregiving husbands showing particularly elevated Framingham Stroke Risk Score scores. High caregiving strain showed this significant association with the Framingham Stroke Risk Score after controlling for demographic factors and other indicators of psychosocial stress, including significant associations between stroke risk and age, educational attainment, and depressive symptoms. Supplemental analyses examining the Framingham Stroke Risk Score components individually found that highly stressed caregivers were significantly younger, on average, than less strained caregivers, but there were no caregiving strain differences on systolic blood pressure.

pressure, use of antihypertensive medication, diabetes, cigarette smoking status, history of cardiovascular disease, atrial fibrillation, or left ventricular hypertrophy.

There are a number of possible explanations for this pattern of findings. Highly stressful caregiving can be chronic and include many difficult and uncontrollable stressors such as witnessing the suffering of a loved one, managing stressful behavior problems, financial strain, social isolation, and providing physically and psychologically demanding personal care tasks.24 Caregiving and other psychosocial stressors can have significant effects on the cardiovascular system,5,11 although we found no differences on the individual variables comprising the risk score in our supplemental analyses. Because younger spouse caregivers were significantly more likely to report high caregiving strain than older spouse caregivers, it appears that the health benefits of relative youth were eliminated by the counteracting health effects of increased caregiving strain. Caregiving strain can also interfere with other health behaviors such as exercising and getting proper rest.5,11 It is not clear why these collective age-adjusted health effects of caregiving strain were observed on measures of stroke risk but not CHD risk. Given the cross-sectional nature of the present findings, it is possible that people high in some stroke risk factors may find caregiving to be more stressful, but then one might expect older caregivers to report more caregiving strain. Prospective research on caregiving strain, incident stroke, and incident coronary events will be critical for further addressing the relationships suggested by these cross-sectional associations.

Highly strained husbands, especially African American husbands, showed the highest estimated stroke risk. Caregiving is traditionally a female sex role, and although many men do take on caregiving responsibilities, role-discrepant responsibilities can increase strain. It is also of interest that, as a group, husband caregivers were much less likely than wife caregivers to report that their caregiving roles were high strain. Male caregivers have been found to use more paid services and have more assistance from extended families than female caregivers,16 which can serve to decrease caregiving strain. In our study, husbands as a whole were less likely to report high strain than wives. Perhaps the subgroup of husbands reporting high caregiving strain are lacking the paid and family assistance that many male caregivers receive when coping with highly stressful caregiving roles.

Our results also replicated some widely reported findings. Greater age, male sex, African American race, less education, and greater depressive symptoms were all associated with higher stroke risk scores. Greater age, male sex, and greater depressive symptoms were also associated with higher CHD risk scores. A strength of our study is that we examined caregiving strain even after accounting for the variance associated with these other factors, some of which (such as depression) are associated with caregiving strain.

Because our results examined stroke risk scores, they must be viewed with caution. Future research should study the association of caregiving strain with incident stroke and CHD, which we will eventually have the capacity to examine within REGARDS. When data are available on incident stroke and CHD, it will be important to look at how factors such as caregiving strain may interact with depressive symptoms, social network, and other variables, because such interaction effects may be more powerful than main effects.25 In addition, the group of highly strained African American males was relatively small, so the very high score in this subgroup should be viewed with caution. It is unclear why caregiving strain was not associated with CHD risk scores, although other demographic and psychosocial risk factors, including age, education, and depressive symptoms, were associated with CHD risk. There are some different variables included in the CHD and stroke risk scores. For example, the stroke risk score includes atrial fibrillation and left ventricular hypertrophy, whereas the CHD score includes total and high-density lipoprotein cholesterol.

Finally, high caregiving strain has already been shown to be a risk factor for depressive symptoms and early mortality.3–6 Highly strained caregivers may benefit from effective caregiver intervention programs, which have been shown to be of similar effectiveness for husbands and wives experiencing highly stressful caregiving.26
